The design of the flap will depend on the need to accentuate the upper pole. If a small amount of breast tissue needs to be resected, it is this flap tissue that is most readily available for trimming.

Technique

After the patient is placed under general anesthesia, we make certain that she is centered on the operating table and that her arms are properly secured so we can sit the patient up for intraoperative assessment of the result. After the patient is draped, we place pendulum sutures at the sternal notch and the xyphoid. Skin staples or Adair clamps can then be used to verify that not too much tissue has been marked for the pillar closure, making horizontal approximation too tight. The nipple is marked with a 42 mm template and then 0.5% lidocaine with 1:200,000 epinephrine is infiltrated to help control bleeding.

After the entire segment between the medial and lateral pillars and the periareolar skin has been deepithelialized, the breast is elevated off the pectoralis fascia. Unless the bases of the pillars are to be trimmed, it is unnecessary to undermine much medially and laterally. However, it is important to dissect up to the top of the superior pole so that the flap can be placed as high as possible.

Once the breast is undermined, a flap is placed in the subpectoral pocket and the medial and lateral cuts are made, isolating the flap on its superior blood supply. The cuts are stopped at the previous mark, which will also represent the 6 o'clock position of the future exteriorized nipple-areola complex. If no implant is to be used, a subglandular dissection is performed. With saline implants, we prefer a subpectoral pocket, but with smaller implants and particularly silicone gel devices, we often use the subglandular pocket.

The flap is then folded underneath into the upper pole and sutured with 2-0 Vicryl pop-offs. The pillars are then reapproximated, beginning at the top, then the most inferior point, followed by a few sutures in between. If the flap has been trimmed off, the undersurface of the gland is sutured as high up in the infraclavicular space as possible. A bite of lateral breast parenchyma is also grasped at the inferior extent of the lateral contour and sutured medially in the midline to help cone the breast and keep it from falling laterally toward the axilla. A 15 Fr Blake drain is placed along the lateral gutter and the vertical portion temporally stapled. Note the upper pole fill and the improved nipple position in relation to the breast mass (*above, right*).

The opposite breast can then be shaped in the same way and to the same point of vertical stapling. Next the patient is positioned upright, and with the nipple template, the final nipple position is marked. Sometimes a temporary periareolar purse-string suture can take up some loose skin in this area before final markings are made with the template. Final deepithelialization is completed, followed by layered skin closure.

The dressing, consisting of large, rectangular sheets of Tegaderm, supports the final breast shape. The nipple should not be compressed by the dressing. We use a rolled-up ABD pad taped into a “hotdog” shape and held in place along the curve of the new inframammary fold using Tegaderm. Although the drain can be removed the following day, the Tegaderm dressing is left in place for 2 weeks.

After the final dressings are removed, the patient is advised to wear a good supporting bra day and night for 8 weeks. Scars are treated with Mederma or Scarguard.

Use of Implants With Mastopexy

The most conservative approach when an implant is also planned is to place the implant first and tailor-tack the skin over the implant to make certain the markings are correct. We prefer to place the implant in the subpectoral position if the patient chooses a saline implant or if the upper pole tissues are excessively thin (pinch thickness less than 3 cm). A silicone gel implant can be placed in the subglandular position with less concern about visibility or palpability. We often use at least a small flap into the upper pole, even in the presence of an implant. The flap can be sutured to the undersurface of the breast itself or to the pectoralis fascia. Rarely is it possible to achieve too much upper pole fullness in a mastopexy.

Selection of saline or silicone implants follows a discussion with the patient and examination of the quality of tissue both skin and parenchyma. Saline implants tend to be more palpable and visible. Because of this, we tend to use saline implants in cases in which the patient prefers them and the skin and parenchyma are thicker. Silicone implants can be used in either position; however, the underlying parenchyma needs to be firm to support the additional stress if the implants are to be placed in the subglandular position. It is always best to scale down the size and dimensions of implants in augmentation mastopexy cases to minimize downward forces on the newly lifted tissues.

Wise Vertical Scar With a Long Horizontal Scar

The Wise pattern vertical scar with a long horizontal scar is based on the reduction technique of the same name. The long horizontal component is necessary to allow adequate resection of the skin envelope. This technique is best suited for women with moderate to severe breast ptosis with poor-quality skin and/or a large amount of skin excess and a moderate amount of glandular tissue. The skin markings are familiar to most plastic surgeons trained in the United States because of the popularity of the Wise breast reduction technique. However, unlike the reduction technique, removal of breast parenchyma is usually not needed.

Proponents of this technique favor the ability to see the final shape while the patient is still on the table and the chance to remove the skin excess, both of which decrease the rate of reoperation. This technique is performed at the expense of longer scars. The horizontal component runs along the inframammary fold from the medialmost

to the lateralmost aspect of the breast, sometimes even farther laterally along the chest wall. The medial limbs must not join in the center of the chest. This area is most prone to hypertrophic scarring and any extension of scar length should not be performed in this direction.

Long-term complications of this procedure include recurrent ptosis or bottoming out of the mastopexy. This occurs because the breast shape is maintained by the skin envelope rather than support from the gland.

Technique

Markings proceed using the standard Wise pattern. With the patient in the upright position, the breast meridian is marked. The level of the inframammary fold is transposed anteriorly to intersect with the meridian to mark the level of the new nipple. The Wise keyhole pattern is spread to encompass the original areola. It is placed so that the superior aspect of the pattern lies 2 cm higher than the level of the new nipple. The markings are checked by pinching together the medial and lateral limbs to assess tension. The closure should be snug to compensate for the eventual skin relaxation, but not tight enough to compromise vascularity. The vertical limbs are extended medially and laterally to intersect with the inframammary fold.

In the operating room, the portion of the areola to be preserved is marked with an areolar marker of the appropriate diameter. The area within the marks is deepithelialized. Transdermal incisions are made along the upper portion of what would be the vertical bipedicle flap of a reduction mammoplasty on either side of the nipple-areola complex. If there is an abundance of deepithelialized breast tissue below the inframammary fold, the gland is dissected off the pectoralis muscle, starting from the inframammary fold and proceeding upward, creating a superiorly based dermoglandular pedicle. The dissection continues until the pocket can accept the excess inferior glandular tissue. This tissue is folded behind the breast and attached to the pectoralis fascia high enough to eliminate gross glandular redundancy. The skin is closed in standard fashion with little or no further undermining. The nipple-areola complex is positioned and sutured into place.

Biologic Meshes

Mastopexy, and more frequently augmentation mastopexy, is plagued with recurrent ptosis. The “holy grail” in this problem involves creation of a durable internal brassiere that is resistant to stretching out over time. This problem is exacerbated when an implant adds weight and strain on breast parenchyma and skin. The use of acellular dermal matrix as well as autologous dermal slings have been used to help create an internal brassiere by reinforcement of the worn-out parenchyma.

Placement of acellular dermal matrix in between implant and breast parenchyma

To correct bottoming out with a dual-plane type of augmentation, dermal meshes can be used as an inferior sling to connect the implant to the chest wall, effectively fixing the location of the inframammary fold and supporting the weight of the implant.

Maxwell and Gabriel have demonstrated the effective use of acellular dermal matrix to correct pocket deformities throughout the breast, whereas Colwell and Breuing have used these dermal matrices in primary mastopexies to have additional support for the stretched-out breast parenchyma. Regardless of the location that these dermal matrices are placed in, they require fixation to stable structures, either the fascia of the pectoralis or the reflection of the inframammary fold. They permit the surgeon to shape the glandular structures more effectively, rather than relying on the skin envelope for long-term shaping of the breast. To minimize complications arising from seroma and/or infection, the surgeon must create a pocket of the dermal matrix that is sandwiched between two vascularized surfaces to maximize vascular ingrowth and incorporation. The drawback to these procedures has been the cost of acellular dermal matrices.

Liposuction

Liposuction has been used to reduce breast size and with concomitant skin retraction, raising the level of the nipple-areola complex. The most obvious benefit is provision of a breast lift with minimal scarring. The preservation of neurovascular structures is another advantage. The limitations of this procedure lie in the fact that the majority of the substance removed from the breast is fat, not breast parenchyma. In addition, the patient must have supple, elastic skin to achieve the greatest benefit.

With the advent of ultrasound-assisted lipectomy (UAL), more-aggressive cases have been tried, because UAL can assist in skin retraction and hence greater nipple elevation than could be accomplished with standard suction-assisted lipectomy (SAL).

The ideal patient for this procedure has mild breast hypertrophy resulting from an overabundance of fat, minimal ptosis, and good skin quality. The indications for this procedure are also expanded to women who have already had a breast reduction procedure and want a small adjustment. The benefits are that further manipulation of the pedicle is avoided, and there is a decreased risk of devascularization and/or nerve injury.

The breast is usually accessed through two small stab incisions above the inframammary fold at the medial and lateral aspects of the breast, and another one at the areola. The placement of these incisions facilitates a more uniform removal of fat by allowing overlap. When this technique is employed correctly, there is minimal risk of damage to the neurovascular supply of the nipple and hence a decreased risk of nipple necrosis and/or loss of sensation.

The main disadvantage of this treatment is its limited application. Only a small subset of women fits the strict criteria for this procedure. On the wrong patient, this technique will produce suboptimal results that may be very difficult to correct.

Technique

The breast should be marked with the patient standing. Contour circles to delineate the areas of greatest protrusion should be used. Standard wetting solution is used (1 L lactated Ringer's solution, 1 ml of 1:1000 epinephrine, and 25 ml 1% lidocaine) when general anesthesia is employed. If the plan is to use local anesthesia alone, the breast may be blocked using up to 100 ml of 0.25% bupivacaine (Marcaine) with 1:400,000 fresh epinephrine and 300 units of hyaluronidase.

Cannula selection usually depends on the experience of the surgeon. Inexperienced surgeons should use a smaller cannula at first to “get a feel” for the patient's tissues and then switch to a larger cannula for major tissue removal. Pretunneling is not required. Care should be taken to avoid inadvertently entering the chest cavity.

The breasts are marked before liposuction. The strategy should promote even resection of fat in areas of excess as well as suctioning of the base of the breast to reduce the breast mound so that the skin can retract more against the chest wall. The goals of suctioning are correction of the hypertrophy and a decrease in the overall weight of the breast. Accurate recording of suction volume is essential to prevent overresection and asymmetry. It is much easier to remove excess tissue later—but virtually impossible to replace overaggressively suctioned breast fat.

Postoperatively, no drains or sutures are used. Absorbent pads are used to catch the drainage. Paper tape is applied horizontally from the bottom of the breast toward the nipple-areola complex, forming a sling under the lower portion of the breast. Then horizontal pieces of paper tape are applied from the superior portion of the breast downward toward the nipple-areola complex. A Reston sponge is applied in half-moon shapes, followed by a snug brassiere. Firm, supportive pressure on the breast is the goal of these dressings. The dressings are removed at 1 week and the patient's bra is placed in a more contoured bra. To help combat any persistent edema, the patient is instructed to wear the bra day and night for up to 6 months.

Mastopexy to Correct the Overaugmented Breast

One of the increasingly common operations that we perform is to revise patients who underwent augmentation years earlier with large saline implants and now have breasts that are too large and too low. Many other presentations can occur, including ptosis with capsular contracture, which can produce bizarre asymmetrical configurations for which a treatment plan is difficult to develop. Some of these patients had large implants placed inappropriately in an attempt to treat breast ptosis by “filling up” the deflated skin envelope because the patient would not accept additional scars. Others have simply gained breast size from a weight increase over the decades.

Our approach to these patients, especially when they have saline implants in place, is to perform a preliminary in-office deflation of their implants to set up the breast for definitive correction. This simple procedure is done with a local anesthetic; an 18-gauge needle is inserted into the implant through the lower pole while compressing the device with the opposite hand until it is completely deflated. The patient then has an opportunity to live with her natural breast shape and size for 3 or 4 weeks while the ligaments shorten and the skin recovers from the overstretched condition. This has the advantage of giving the patient the opportunity to decide whether she even needs or wants additional implants as well as shape correction with a mastopexy. Some patients have a satisfactory shape and can simply undergo reaugmentation, usually in a new plane, and their implants are often replaced with silicone gel devices.

Many of these reoperative patients have the idea that they must have implants to give them the shape they want, but the two-stage approach allows them to see that they have adequate parenchyma to produce breasts of suitable size if a mastopexy alone can be performed. It is much easier to plan the definitive correction after implant deflation than to try to accomplish everything in a single stage. This approach decreases the chances of the patient’s needing yet another revision.

Postoperative Care

Postoperative care following a mastopexy starts in the operating room. Because of our preference for parenchymal reshaping to maintain a more permanent result, the breast should be held in its exaggerated shape for the first several weeks after surgery; that is, the fullness of the upper pole, with a flattened lower pole shape, must be splinted to assist in solid internal healing to keep the breast shape high and round.

The use of Tegaderm has been exceedingly helpful in this regard. We use large sheets cut longitudinally so that two long, narrow sheets can be used as a clear, supportive dressing. Care must be taken not to pull the Tegaderm over the skin, because this will create shear forces that can cause blistering. Rather, the breast is held in the desired position and the Tegaderm is simply laid down flat against the skin to hold it in place. The first sheet goes from lateral to medial, from the nipple down to the inframammary fold. This material can also be used to support the drain and maintain its position. The second sheet goes across the upper pole, overlapping the lower sheet at approximately the level of the nipple. We usually cut out a small segment to avoid flattening the nipple. A rolled-up ABD sponge taped into a large “hotdog” shape is used to accentuate the pressure curving along the new inframammary fold. This sponge is held in place with a half-sheet of Tegaderm. Next, we place the patient in a support bra, which helps maintain the final shape. An advantage of using Tegaderm is that when the patient takes off the bra, she can shower normally without losing support.

The drain is ordinarily removed on the first postoperative day. With a smaller mastopexy, we may choose not to use a drain at all. Typically, a mastopexy procedure is not associated with anything more than minor pain. Oral analgesics are sufficient, and ketorolac tromethamine (Toradol) has also been helpful in patients who are sensitive to narcotics.

The patient is seen 1 week after drain removal. At this time a small amount of the Tegaderm is removed around the edge of the areola, and the interrupted nylon sutures are removed. At 2 weeks postoperatively the patient returns after removing all of the remainder of the Tegaderm in the shower in the morning. The breasts are simply gently washed, patted dry, or dried with a hairdryer, and the patient puts the support bra back on.

We recommend that the patient wear a support bra day and night for 8 weeks following mastopexy. “Push-up” bras that accentuate the upper pole are helpful during this period to encourage the breast to heal in a high, round position.

Scar treatment begins 3 weeks postoperatively with such over-the-counter preparations as Mederma or Scarguard. An underwire bra often helps define the new inframammary fold shape and position. Typically, we do not consider scar revisions for 1 year after surgery, although if a small amount of redundant tissue exists at the inferiormost portion of the vertical scar at 6 months postoperatively, we may consider a small revision in the office if the patient is unable to wear a swimsuit or is uncomfortable with it.

Outcomes and Complications

Although patients who undergo mastopexy always look better than they might have looked had they not had the operation, the result must be considered semipermanent. Invariably, a little shape is lost over time, and the nipple descends. If bottoming out occurs, the nipple position may be disproportionately high. These shape issues are ordinarily addressed at 1 to 2 years postoperatively to let the shape settle before any revision is offered.

This 37-year-old woman underwent vertical mastopexy to treat pseudoptosis. Notice the error on the right in placing the nipple too high on the breast mound. She is shown before and 1 year after surgery. The lateral views show the considerable breast elevation that has been achieved, clearly demonstrating that the nipple position is too high.

Bleeding and infection are rarely seen after a mastopexy. Nipple and areolar deformities can usually be prevented by avoiding tension on the closure. We do not excise too much skin and make certain that the pedicle moves freely to the new nipple position. If the scar is wide or the shape of the areola is irregular, these problems can be corrected rather easily by reexcision and closure in the proper shape.

As in the case of reduction mammoplasty, breast-feeding following mastopexy may or may not be successful. In patients who do become pregnant after mastopexy, we encourage them to try breast-feeding, but to be aware that they may have to supplement the nutritional needs of the baby. It is important to advise patients that additional corrections may be desirable when pregnancies occur after mastopexy.

It is not uncommon to encounter some problems with implant malposition when a mastopexy is done concomitantly. As opposed to breast augmentation alone, where malposition problems may be addressed as early as 3 months postoperatively, we are reluctant to correct the augmentation-mastopexy patient for at least 6 months, because we have seen many cases in which the deformity either improves on its own or is not fully stabilized during this time frame. Of course, correction of these problems is aimed at either changing the level of the implant by capsulotomy or capsulorrhaphy or revising the mastopexy if the implant is in the proper location. Typically, mastopexy revisions are possible by skin-only techniques.

Chronic pain following mastopexy can be enigmatic. Occasionally this is caused by ongoing fibrocystic breast disease, chondrochondritis, or sutures that have inadvertently encircled sensory nerve fibers. The latter is usually diagnosed by pinpoint tenderness laterally with shooting pain and can be attributed to the neuroma. A small amount of lidocaine or bupivacaine in the area is usually diagnostic. Fortunately, this usually resolves without treatment.

Most patients remain pleased with mastopexy results, particularly as the years go by and the scars fade. We have seen patients in whom the scars become virtually invisible. Late tanning (more than 9 months postoperatively) appears to help fade the scars. If the shape remains satisfactory, the scars are well accepted by most patients.

Results

This 44-year-old patient had tissues that were very fatty without much glandular substance. An implant was obviously necessary to lend adequate volume and shape. Additional factors included lack of support from any type of glandular flap. Therefore the plan included placing an implant with an appropriate base diameter. This patient chose saline; however, our preference is a round or shaped silicone gel device in most cases. She is shown 1 year after placement of a saline-filled implant with a final volume of 360 cc in the subpectoral position and a skin-tightening vertical mastopexy.

In this 40-year-old patient, we considered adding an implant, but because she could create her desired shape and size in a bra, we decided a mastopexy alone was all that was needed. She underwent a vertical mastopexy in which the superiorly based parenchymal flap from the lower pole was folded underneath the upper pole to create some additional upper pole convexity. She is shown 7 months postoperatively. If this patient desires additional fullness, an implant can be added later after the mastopexy is healed and stable.

Preoperative

9 months postoperatively

2 years postoperatively

This 38-year-old woman had an unusual asymmetry condition in which the larger breast had a higher, smaller nipple-areola complex. Both breasts required a mastopexy to reshape the parenchyma; the plan included reducing the volume on the left so that the parenchymal volumes could be equalized. This approach allowed equal sized and shaped implants to be placed. When the ratio of breast parenchymal volume to implant volume and dimensions is equal, the evolution of shape over time is much more likely to result in a long-lasting, symmetrical correction.

The correction included an autoaugmentation with a superiorly based parenchymal flap on the right with a 150 cc smooth silicone gel implant. On the left breast, a 154 g reduction was done in the inferior pole, and a 150 cc silicone implant placed.

Although her result was satisfactory at 9 months postoperatively, by 2 years there was a worsening of the shape on the right. This was associated with a 5-pound weight loss that was significant in this very petite patient.

This 37-year-old woman underwent a vertical mastopexy with a small, 200 g reduction. The patient is shown before and 1 year after surgery.

This 36-year-old woman presented with asymmetry. She is shown preoperatively and 3 months after vertical mastopexy in which 30 g of tissue was resected from the right and 200 g from the left breast.

This 42-year-old woman underwent explantation of 360 cc saline implants and subsequent vertical mastopexy. She is shown preoperatively and 9 months postoperatively.

This 47-year-old woman had severe ptosis and glandular excess. An inverted-T reduction with superomedial pedicle was performed. She is shown before and 4 years after surgery.

This 43-year-old patient who had a previous augmentation mastopexy underwent explantation of 200 cc implants and then mastopexy with an inverted-T pattern. She is shown before and 9 months after surgery.

This 24-year-old woman had macromastia as well as breast asymmetry, with the right side larger than the left; 100 cc of tissue was aspirated from the left breast and 350 cc from the right. She is shown before and 1 month after liposuction.

This 37-year-old woman was treated for severe ptosis. A Wise pattern mastopexy with a superior pedicle was done. No reduction was performed on the left breast, and 100 g of tissue was resected from the right. She is shown before and 3 months after surgery.

This 57-year-old woman had moderate ptosis and breast atrophy. Augmentation with 275 cc implants was performed, followed by vertical mastopexy. She is shown pre-operatively and 1 year postoperatively.

Concluding Thoughts

At present, all mastopexy techniques are imperfect. Although surgeons are doing a better job of reducing overall scar length, we still struggle to obtain a beautiful, stable, long-term shape that will justify the scarring. Most women will accept the scars if the shape is attractive. The periareolar techniques work best if the breast tissue is relatively fibrous and the skin is good. We await the development of a suitable internal mesh to use in the Góes technique. In the meantime, we have found that the vertical techniques provide the best, most predictable results, with or without the use of implants.

Clinical Caveats

Periareolar Mastopexy Without Parenchymal Reshaping

This technique is suitable only in mild to moderate ptosis cases in which a minimal amount of elevation is required.

The amount of nonpigmented skin excision should be less than the amount of pigmented skin.

Benelli Periareolar Mastopexy Technique

The surgeon should start with mild to moderate ptosis cases until he or she is more familiar with this technique.

Although this technique can be applied to more advanced degrees of ptosis, it has its limitations in treating patients with severe ptosis and/or poor-quality skin.

The best results are with patients without striae and with dense fibroglandular parenchyma.

The amount of skin removed should be limited to decrease the resultant periareolar scalloping.

Tension on the parenchymal sutures should be avoided to preserve maximal glandular and nipple areolar circulation.

Góes Periareolar Technique With Mesh Support

The surgeon should accept a slightly larger areolar size in relation to the base width of the breast.

The amount of skin removed lateral to the nipple-areola complex should be limited.

Flap dissection should be performed very carefully so that the skin flaps drape smoothly over the mesh.

The space between the mesh and skin should be drained for at least 1 week.

The original mesh used (Vicryl/Dacron) is no longer available. The current preferred mesh is Vipro, manufactured by Ethicon.

Vertical Mastopexy Without Implants

The nipple position is set approximately 2 cm below the usual *A-point*. (The A-point in breast surgery refers to the anterior projection of the inframammary fold onto the breast. With inverted-T techniques, this represents the position of the new nipple. With vertical mastopexy, it represents the top of the areola.)

The surgeon should be cautious in marking the medial and lateral pillars, keeping in mind that minimal if any breast tissue will be excised.

Parenchymal shaping sutures are used in the superior pole and in the lateral pillars to assist in shaping the breast.

The new nipple-areolar position is marked with an areolar template with the patient in the upright position before final suturing.

Securing the breast with either Tegaderm or Micropore paper tape for 2 to 3 weeks helps to mold the final breast shape.

Liposuction Only

The key to success with liposuction is correct patient selection.

The ideal patient is one in whom the nipple-areola complex is already in a good position.

Liposuction-only candidates should have a majority of fat rather than fibroglandular tissue.

Wise Pattern

The surgeon should attempt to tailor the horizontal component of the scar within the new inframammary crease to help camouflage it.

The pattern is useful for reoperative cases when the breasts have been overaugmented.

A two-stage approach is planned with in-office deflation at least 4 weeks before the definitive correction.

The surgeon meets with the patient 1 week before the final correction to determine whether an implant is needed, and if so, what type and size.

Continued

Clinical Caveats—cont'd

Biologic Meshes

Biologic meshes are useful adjuncts in primary cases in which the breast parenchyma and skin are very stretched out.

Mesh is invaluable in revisional cases of augmentation mastopexy where the breast parenchyma is lacking.

The correction must be good while the patient is still on the operating table, because there will be very little settling over time.

Ideally, a “lamellar” structure will be created to coapt acellular dermal matrix to vascularized tissue, such as a skin flap and/or breast parenchyma.

These matrices must be drained to avoid seroma and to enhance the revascularization and incorporation of the matrix.

The greatest drawback is the cost of acellular dermal matrix.

CHAPTER 68

Breast Reduction: *The Medial Pedicle Technique*

ELIZABETH J. HALL-FINDLAY

The key to the medial pedicle vertical breast reduction technique is less about creating shorter scars than it is about understanding its fundamental concepts. Most inverted-T breast reduction approaches remove a horizontal ellipse of skin and breast tissue that when closed leaves medial and lateral dog-ears. Most vertical approaches remove a vertical ellipse of skin and breast tissue and when closed leave superior and inferior dog-ears. Removal of an inferior vertical wedge of breast tissue allows the surgeon to not only narrow and cone the breast but also to remove the heavy inferior breast tissue, leaving behind the superior breast tissue.

There are multiple vertical approaches and numerous pedicle choices. I prefer the medial pedicle because it has a good blood supply, the pedicle rotates easily into position without kinking or compression, and the retained sensation is equivalent to that of the other available pedicle approaches. The inferior border of the medial pedicle becomes the medial pillar so that, as it rotates into position, it leaves an elegant curve to the lower pole of the breast.

It is essential to understand that the medial pedicle vertical breast reduction uses the Wise pattern as a good breast (brassiere) design for the pattern of the parenchyma that should be left behind rather than for what should be removed. Once the vertical wedge is removed and the breast is coned, all breast tissue inferior to the Wise pattern is removed either directly or with liposuction. The skin is then allowed to re-drape over the newly shaped breast mound.

The belief that surgeons must choose between scars and shape is not true. The medial pedicle vertical breast reduction not only results in reduced scars but also maintains a good, long-lasting breast shape. The surgery takes less time, blood loss is less, and

the recovery is faster. In my experience, the incidence of complications is also significantly lower with vertical breast reductions than with inverted-T inferior pedicle breast reductions. There are more pucker revisions with the vertical approach, but that is partly a function of being easily able to perform a revision and the surgeon's threshold for revision. Many patients who undergo inverted-T procedures are told that the lateral and medial dog-ears cannot be corrected, and this makes the revision rate low.

Evolution of Technique

When I first tried vertical breast reduction techniques in 1993, I could see that there was a definite improvement in shape, but I had problems with the superior pedicle; it could be difficult to inset, and I did not understand the blood supply. I thought it would be better as a full-thickness pedicle, but in fact, it is safer and less likely to be compressed when it is thinned. The problem with thinning the superior pedicle is that it leaves an empty space underneath, which tends to leave a concave inferior pole for a few weeks after surgery. The medial pedicle is easy to inset, and the shape of the breast while the patient is still on the operating table is quite good.

I then tried a lateral pedicle, because I thought it would have the best chance of retaining good sensation, but again, I did not really understand the anatomy. The problem with the lateral pedicle is that the tissue that forms the base of the pedicle is exactly the same tissue that needs to be removed to produce a good reduction and an aesthetic breast contour. I could see that the medial pedicle gave a better shape, but I was also surprised that the medial pedicle produced excellent recovery of sensation.

In this patient a lateral pedicle was used on her right side and a medial pedicle on the left. She had good return of sensation in both breasts. The problem with the lateral pedicle is that the base of the pedicle prevents good resection of the excess lateral breast tissue.

Advantages and Disadvantages

The advantages are in the reduced scarring and better shape, and when surgeons realize that *they do not need any tension on the skin closure*, the wound-healing problems and complications are dramatically reduced.

Another advantage is that the concept of the medial pedicle and vertical parenchymal resection can be used in much larger breast reductions, even when an inverted-T skin resection pattern is needed to reduce the redundant skin. Skin does not need to be removed as often as surgeons think, but some patients have far too much skin, or too much skin of poor quality. The advantages of the medial pedicle with the inferior resection can still be preserved, even when the final closure has increased scarring with a T, J, or an L.

The disadvantage of the medial pedicle vertical breast reduction is that inevitably nipple necrosis will occur in some cases. I believe that there are four main arterial supplies to the breast, and sometimes only three of the four are dominant. We cannot determine preoperatively which pedicle will be safe. I believe that nipple necrosis is inevitable in a large-volume practice, and it is more likely to be a statistical occurrence rather than a result of bad surgery.

Indications and Contraindications

The best candidates for a medial pedicle vertical breast reduction are young, healthy women who need a small- to moderate-sized breast reduction. There is more of a learning curve for the larger reductions, but the method is still excellent. However, there is a point at which an inverted-T skin resection pattern will be needed, but this point is not nearly as early as some surgeons envision.

The best results in all breast reductions are achieved in women who are not overweight; the cosmetic result is not as good in heavy or obese patients. In some very large-breasted women, any of the pedicles chosen will be long. Theoretically, the blood supply stretches with the breast as it grows and becomes ptotic, but the reality is that nipple necrosis is more likely with the longer pedicles. The other problem

with excessively long pedicles is their sheer volume, which limits the size of the reduction and increases the weight of the breast in the lower pole. This extra weight can be sutured up onto the chest wall, but it will tend to bottom out with time.

Some patients who have large breasts, good nipple position, and a large proportion of fat to gland may be better candidates for liposuction-only breast reduction (see Chapter 71).

Patient Profiles

This patient is young and healthy, and close to her ideal body weight. She needed a moderate-sized breast reduction and was a good candidate for a medial pedicle vertical breast reduction, which was especially fortunate, because she turned out to be a bad scar former.

This older woman is a less than an ideal candidate because she has very large breasts, and her cosmetic result will not be ideal, because she is not close to her ideal weight. A further reduction might be indicated to reduce some of the volume that still exists in the lower pole.

Pertinent Anatomy

Blood Supply

The blood supply to the breast is mainly superficial; the arteries and veins are in the subcutaneous tissue that was pushed outward as the breast developed. The breast is a skin-derived subcutaneous structure that is attached loosely to the skin (and firmly at the nipple). It is only very loosely “attached” to the chest wall. These attachments are easily swept away with a finger during a subglandular breast augmentation. The breast is held in place by fascial condensations inferiorly (the inframammary fold) and medially (over the sternum). These act much like the gluteal fold and the sacrum. The breast moves easily over the chest wall, is quite mobile, and is not held in place either superiorly or laterally.

When a woman lies on her side, the upper breast folds over the sternum medially and the lower breast slides out. Only the lower breast border (inframammary fold) and the medial breast border are relatively fixed structures holding the breast in place.

The artery to a superior pedicle comes (usually) from the second intercostal space; it descends and enters the nipple area just medial to breast meridian and is always about 1 cm deep to the skin. It bleeds with significant force when cut during creation of a medial pedicle; it can be traced with a pencil Doppler preoperatively. The artery to the medial pedicle also comes from the internal mammary system (usually from the third intercostal space); it curves around the sternum, penetrates the pectoralis, and is pushed outward with the subcutaneous tissue.

The deep system then comes from the fourth intercostal space and enters the posterior aspect of the breast as it perforates the intercostal muscles and the pectoralis. It enters the breast just medial to the breast meridian. It has accompanying venae comitantes, and these vessels are all cut when a medial pedicle vertical breast reduction is performed. It is this artery (and branches) and veins that are enclosed in the septum described by Würinger et al. This is the blood supply to an inferior or central pedicle.

The fifth and sixth intercostal arteries from the internal mammary system also enter the breast just above the inframammary fold and add extra security to an inferior pedicle. Many of these lower vessels are cut during creation of a central pedicle.

The only other blood supply is the superficial branch of the lateral thoracic artery; it can be seen curling around the pectoralis and entering the lateral aspect of the breast. It supplies a lateral pedicle.

It is interesting that the veins do not accompany the arteries except for the deep perforator; they can be seen just under the dermis and drain mainly superomedially. That is why I no longer infiltrate my incision lines—I kept hitting veins and causing small subcutaneous hematomas.

Innervation

Although the main innervation to the nipple may come from the lateral branch of the fourth intercostal nerve, there is no question that good innervation comes from all four quadrants of the breast. It appears that all the pedicles—lateral, medial, superior, inferior, and central—all have fairly equivalent sensation. I tell my patients that about 85% of patients will recover normal to near-normal nipple sensation. However, they are all warned that they may lose feeling completely in the nipples.

Most of the glandular breast tissue is concentrated deep to the nipple-areola complex and laterally in the upper-outer quadrant. The medial aspect of the breast has some glandular tissue but a higher proportion of fat.

Preoperative Assessment

A key ingredient to a successful breast reduction operation is patient education. I have a detailed handout to give to patients; the contents are reinforced with a DVD and a group PowerPoint session. It is essential to make patients understand what can and cannot be achieved. I make certain that patients comprehend the concept of *high-breasted* and *low-breasted* and that I cannot surgically change the breast footprint, or where the breast sits on the chest wall.

I find that taking photographs during the consultation and marking them for the patient is very helpful. I can show the patient where her upper breast border is and reinforce that I cannot change it. I also draw on the lateral view to show her that she will still have some ptosis; I warn all patients that they will still be able to hold at

least one pencil underneath the breast. I can only change the lateral and inferior excess along with narrowing the base diameter. Patients often think that they have no upper pole fullness because they see their breasts as “flat,” but then I can show them with the pinch test and the drawing that they can get more projection (or perkiness) with a medial pedicle vertical breast reduction.

The patient on the left is high-breasted, with good upper pole fullness; the patient on the right is low-breasted, with poor upper pole fullness. Not only do both patients require different surgical approaches, but also they need to have very different expectations.

The patient on the left has a high upper breast border but a low inframammary fold level. She has a high breast footprint, but it is long vertically. The patient on the right has a high upper breast border and a high inframammary fold level. She has a high breast footprint, but the footprint is relatively short vertically.

The patient on the left has a very low upper breast border and an inframammary fold level that is actually below her elbow crease. She has a low breast footprint that is long vertically. The patient on the right has a very low upper breast border but a very high inframammary fold level. She has a low breast footprint that is actually very short vertically. (Not all numbers shown on these patients are necessary for surgical marking; some are done for preoperative and postoperative measurement for later assessment purposes.)

My examination consists of assessing the breast footprint—the upper, lateral, medial, and inferior breast borders—and then the third dimension—how the breast sits on that footprint. Does the patient have good upper pole fullness? If so, a better cosmetic result can be achieved. If a patient has a great deal of ptosis and a poor upper pole, it will be futile to try to push the excess inferior breast tissue into the upper pole, because it will just drop down again. I can visualize how long the pedicle might be and whether I need to warn the patient about a possible free nipple graft (very rare). I assess the skin quality and skin excess and again determine whether I need to warn the patient that I might need to add a “hockey stick” to their vertical scar.

The results in these two patients will be very different with any type of breast reduction. The patient on the left not only has a high breast footprint, but she also has excellent upper pole fullness. The patient on the right has a low breast footprint and very poor upper pole fullness. Any attempt to push tissue into the upper pole is doomed to failure over time.

It is important to decide preoperatively how much tissue will need to be removed. Any attempt to push *AB* out to *C* will inevitably result in the loss of *BC* and will cause bottoming out.

The problem of bottoming out is illustrated in this patient. Although the nipple was clearly placed too high, there is still too much tissue in the lower pole. This example of bottoming out is the fault of the surgeon (me)—not the procedure. A patient like this provides the surgeon with a very difficult challenge.

Although it is tempting to elevate the upper pole of the breast and suture the breast tissue up to the chest wall to elevate the upper breast border or to achieve more upper pole fullness, results will be disappointing.

It is important to understand some definitions. The *upper breast border* is at the junction of the chest wall and the breast. Sometimes this is well demarcated, and sometimes it is a gentle slope. *Projection* is the measurement from the chest wall to the anteriormost projecting part of the breast. This is where the nipple is ideally situated.

The upper breast border is clearly demarcated in this patient. Although projection is definitely improved, there is no improvement in upper pole fullness or elevation of the upper breast border.

This patient shows that the initial improvement in upper pole fullness achieved by suturing breast tissue up to the chest wall is lost over time.

I tried elevating the upper breast tissue and suturing it higher on the chest wall in 77 patients. I used absorbable 3-0 PDS in 43 patients and nonabsorbable 3-0 Ticron in 34 patients. In the 72 patients who returned for follow-up, none of the initial improvement lasted for more than 5 months. The upper breast border remained unchanged, and the upper pole dropped back to its original position. Projection, on the other hand, was definitely improved.

Improvement in upper pole fullness can occasionally be obtained by using the method popularized by Ruth Graf (see Chapter 72). This takes the inferior wedge of breast tissue that is normally removed in a breast reduction and uses it as a chest wall-based flap that is held in place by a strip of pectoralis muscle. Using this vertical wedge as a flap was originally described by Liacyr Ribeiro, and it is a good method for rearranging the breast tissue in a mastopexy. The pectoralis loop is effective at holding the wedge of breast tissue higher on the chest wall, and it definitely improves projection and can help fill the upper pole to some degree.

I also warn patients that I often cannot make their breast as small as either of us would like. I cannot achieve as significant a reduction with the vertical approaches as I could when I performed inverted-T inferior pedicle reductions. The photographs taken during the consultation are also useful for pointing out any asymmetries and warning patients that symmetry is a goal but impossible to achieve. Patients are also warned that breasts will change with time, gravity, pregnancy, weight gain, and weight loss.

Teenagers are well aware that their breasts might grow as they continue to develop and that a re-reduction might be indicated. I think that this is far better for many teenagers than having them suffer until they are older, because they tend to withdraw and stop participating in sports and other activities if their breasts are large. As long as the teenager understands the procedure and its limitations, I am fully prepared to perform the surgery when it is physically indicated. The same applies to older patients. It is not age that matters; it is the health and the psychological maturity of the patient.

Preoperative Planning

Much of preoperative planning consists of patient education. A preoperatively informed patient is a surgeon's best ally.

Markings

Upper Breast Border and Inframammary Fold

I start by marking the upper breast border (the junction of the chest wall and the breast). This is sometimes a very clear demarcation, and sometimes it is less well defined. The upper breast border is often at the top of any striae that may be present. I then mark the inframammary fold.

I have marked the upper breast border of this patient with a dashed line. She is high-breasted, with good upper pole fullness. The lowest point of her inframammary fold is marked on the midline of the chest wall, with the right fold being slightly higher than the left. The breast meridian is marked where it is expected to be once the reduction is completed.

Ideal Breast Meridian

The breast meridian should be marked at its ideal or desired position, not at its existing position. Sometimes the nipples are too medial, and sometimes they are too lateral. It is best to err on the side of placing the meridian slightly lateral to a line that would bisect the resulting breast after the reduction is performed. More of the lateral breast tissue can be removed with the medial pedicle vertical breast reduction, so the line can be placed slightly more medially than one would in an inverted-T breast reduction. It does not matter where the line starts at the clavicle, but it should be at the midline of the breast at the level of the new nipple position. This will usually be about 8 to 10 cm from the midline of the chest wall.

In the patient on the left, the new meridian does coincide with the existing meridian. In the patient in the middle, the existing meridian would be too medial. In the patient on the right, the existing meridian would be too lateral.

The surgeon should place the new meridian just lateral to the line bisecting the resulting breast, because nipples placed too medially look odd. On the other hand, the medial pedicle vertical breast reduction removes more of the lateral breast and narrows the breast cone better than the inverted-T procedures, and the meridian can be drawn a bit more medially than in an inverted-T reduction.

New Nipple Position

The new nipple position should be on the new breast meridian, about 8 to 10 cm below the upper breast border. The surgeon should position the nipple too low rather than too high, because a nipple placed too high is almost impossible to lower post-operatively, but it is easy to elevate a nipple that has been placed too low. It is better

to mark the new nipple position in relation to the upper breast border rather than to the inframammary fold. The fold itself is a good landmark in many patients, but it can be misleading in about 15% of patients.

Marking the new nipple at an arbitrary distance from the inframammary fold or the clavicle will also result in problems, especially in low-breasted patients. In the illustration on p. 2457, the new nipple position has been marked higher than the inframammary fold because the woman is high-breasted and has good upper pole fullness. The surgeon should be careful to lower the nipple position in a patient with very poor upper pole fullness. It is difficult to lower a nipple that has been placed too high.

Areolar Opening

The top of the areolar opening should then be marked about 2 cm above the new nipple position. Most areolae are designed to result in a diameter of about 4 to 5 cm. The areolar opening can easily be drawn freehand and then pinched at the bottom to make certain that it forms a circle when closed.

Care should be taken to ensure that the areolar-opening markings match from one side to the other.

Skin Resection Pattern

The skin resection pattern follows the vertical lines that would be used in an inverted-T Wise pattern breast reduction. Instead of carrying the vertical limbs laterally and medially, once 5 cm is reached, they are joined together well above the inframammary fold.

These lines will match up with the breast and chest wall meridians when the breast is rotated medially and laterally. The surgeon can pinch the lines together to make certain that not too much skin is being removed. Since a medial pedicle vertical breast reduction does not use the skin as a brassiere and tension on the skin closure only causes wound healing problems, it is better to be conservative with the skin resection pattern and not take too much skin.

The lines need to be joined at least 2 to 4 cm above the inframammary fold. This is not only because closure of an ellipse lengthens the scar but also because the inframammary fold often rises. If the lines are brought down to the fold, the scar will inevitably end up on the chest wall. It is also important to make the skin resection pattern as a U rather than a V. It may be tempting to create a V, because it may seem to avoid a pucker more easily, but in fact the opposite can occur—a postoperative pucker is more likely to be the result of excess subcutaneous tissue rather than skin. It is more difficult to remove enough of the inferior subcutaneous tissue when a V is designed.

Medially Based Pedicle

The medially based pedicle is best drawn with half of the base in the areolar opening and half on the vertical limb. The inferior border of the medial pedicle will become the medial pillar. The base of the medial pedicle is usually about 6 to 10 cm.

It is wise to try to incorporate one of the veins that are visible through the skin in the base of the pedicle, especially when the pedicle is long. A true “superomedial” pedicle can be designed to take advantage of the descending artery from the second interspace. It usually enters the areolar opening just medial to the breast meridian, but it will be missed in this patient. This patient has a very short pedicle so a pure medial pedicle can be used. A pure medial pedicle is often called a superomedial pedicle, because it looks that way when a patient stands up.

A true superomedial pedicle has a base that crosses and extends slightly lateral to the breast meridian. This will make the pedicle more difficult to inset, but because the blood supply is superficial, the surgeon is free to debulk the area deep to the breast meridian if the pedicle is stiff or difficult to inset. This maneuver can preserve the descending artery that normally supplies a superior pedicle.

Areas to Be Liposuctioned

Any areas past the breast borders that are to be liposuctioned are then marked. A different patient is shown above with the lateral chest wall areas and preaxillary areas marked for liposuction. The indented area just below the preaxillary fullness is marked with X's as an area to avoid resection either directly or with liposuction.

This shows difference between the vertical markings in blue (which resemble a snowman) and the Wise pattern inverted-T red markings. Although the nipple should actually be placed lower in a vertical approach (to accommodate the increased projection), the markings are clearly fairly similar. I will remove all parenchyma (except the medial pedicle) below the red lines, but I will only remove the skin within the blue lines. The idea is to leave parenchyma attached to the skin above the red lines, leaving behind the Wise pattern.

The Wise pattern is a good design for what should be left behind. The skin does not usually need to be removed in the same pattern, but it can be allowed to redrape over the new breast shape. The skin is not used as a brassiere, so closure does not need to be tight.

The Wise pattern, once brought together, nicely cones the remaining breast tissue. The surgeon should keep this shape in mind when performing the resection. It is a good design for what should be left behind.

These images show how the surgeon can visualize what will be left behind and how the shape is coned with an inferior vertical wedge resection when the medial and lateral pillars are brought together. Everything beyond the Wise pattern is removed either directly or with liposuction.

The crosshatched areas shown are where liposuction is to be performed.

Operative Technique

Positioning

The patient is placed supine on the operating table with the arms angled outward. For surgeons who wish to position the patient upright at the end of the procedure, the arms should be carefully wrapped and the patient positioned on the table so that her back can go up in the right position.

Infiltration

I no longer infiltrate the incision lines, because I want to preserve any veins that are found just below the dermis. I infiltrate the areas to be suctioned with either a tumescent type of fluid (1 L Ringer's lactate with 1 ml of 1:1000 epinephrine and 20 ml of 2% plain lidocaine) or lidocaine with epinephrine (20 ml of 1% lidocaine with 1:200,000 epinephrine diluted with 60 ml of saline solution). I use approximately 300 to 500 ml of tumescent fluid per side, or about 40 ml of the lidocaine with epinephrine per side. Most of the infiltrate is placed in the lateral chest wall, preaxillary areas, and just above the inframammary fold. These are the areas where most of the liposuction is performed.

Pedicle Creation

The pedicle is deepithelialized in the usual fashion by placing a lap pad around the base of the breast and holding it with a Kocher clamp. This puts the skin under tension and allows it to be removed more easily. The medial pedicle is much easier to deepithelialize than an inferior pedicle. A cuff of tissue is left around the new areola using the Schwartzman maneuver.

Even when the nipple is high and contained within the areolar opening, I still prefer a medially based pedicle. This not only allows me better access to the excess lateral breast tissue but it also maintains the elegant curve to the lower pole of the breast because the inferior border of the medial pedicle becomes the medial pillar.

The pedicle is then cut straight down to chest wall to create a full thickness pedicle. The blood supply is superficial but keeping it full thickness allows preservation of sensation and ductal tissue.

Parenchymal Resection

The pedicle creation and parenchymal resection are performed together, with the pedicle remaining full thickness and the resection being performed en bloc. The arrows above show the lower limits of the pillars. The left arrow shows the inferior border of the medial pedicle, which, when rotated up, becomes the medial pillar. Both pillars will be about 7 cm long in an ideal C cup breast.

Because the pedicle will tend to be thin at the distal end (not because it is actually thinned, but it will appear to be thinned much like an inferior pedicle), it is important to leave a small platform of tissue superiorly and laterally to help prevent post-operative areolar retraction. However, this tissue cannot be pushed up into the upper pole to try to increase upper pole fullness, because it will drop back down again.

The breast tissue is removed laterally by beveling out the resection after leaving behind a 2 cm lateral pillar that is about 7 cm long. The parenchyma beyond that is then removed by beveling out under the lateral flap and removing tissue parallel to the chest wall. If the patient has very thick glandular breast tissue (many teenagers, for example), this tissue must actually be carefully carved out, making certain not to leave any ridges behind. Breasts that have a higher fat content will be more forgiving. It is often difficult to make breasts small enough when using a medial pedicle vertical breast reduction, and it is this lateral breast tissue that needs to be more extensively resected.

It is important to remove all breast tissue below the Wise pattern and this includes removing tissue by undermining down to the inframammary fold. I find it easiest to grasp this extra tissue with a Kocher clamp and then resect it. It is important to leave enough fat on the dermis so that postoperative scar contracture does not occur. Tissue is removed all along the inframammary fold both medially and laterally. Some of this tissue is quite fibrous and will need to be directly excised. It can be complemented with liposuction, which is usually performed after closure of the pillars and the deep dermis.

With the resection complete, it can be seen that the pectoralis fascia is not exposed. The pedicle is being held up by a skin hook. Exposure of the pectoralis muscle can not only cause more bleeding but it can also damage some of the nerves that supply the nipple. The deep branch of the lateral fourth intercostal nerve travels just above the pectoralis fascia and then turns up toward the nipple at the breast meridian. The surgeon should exercise care not to damage the pectoralis fascia and keep the pedicle full thickness to preserve this nerve.

The arrows in these photos show the inferior aspect of both pillars. It can be seen that the inferior border of the medial pedicle becomes the medial pillar. The pillar sutures start at the level of the arrows about 1 or 2 cm deep to the skin. I use 3-0 Monocryl to close the pillars; only about three or four sutures are used. It is not necessary, and in fact is contraindicated, to try to mobilize lateral tissue and close it under tension. The pillar closure should have very little tension. The pedicle can be pulled up during closure to make certain that the pillar can be better visualized. It might be advisable to suture extra long pedicles to breast tissue to help hold them there while healing occurs. Large, deep bites are not necessary; pedicle sutures are only needed so that fibrous-type tissue can heal to fibrous-type tissue.

The deep dermis is closed and then liposuction is performed in the areas marked. It is easier to close the deep dermis first to provide some resistance when performing the liposuction. The breast that remains behind has a Wise-pattern shape.

The areola is closed with four interrupted deep dermal sutures. The areola is sutured into place in the position in which it seems to sit the most easily without any kinking. Both the deep dermis and the subcuticular closure are completed using 3-0 Monocryl. The vertical incision is not gathered. When vertical breast reduction was initially introduced, it was thought that the vertical incision could and should be kept short by cinching up the closure. This did not work, however, because the incisions stretched back out (and if they didn't, they required revision). Not only did it not work, but the extra length is actually necessary to accommodate the extra projection that is achieved with a vertical approach. A B cup breast will have a vertical length (from the lower edge of the areola to the inframammary fold) of about 7 cm, a C cup breast will have a length of about 9 cm, and a D cup breast about 11 cm.

This illustration demonstrates how a longer vertical length from the bottom of the areola to the inframammary fold is actually desirable. A 5 cm vertical length results in a flattened breast with very little projection.

In these photographs it is evident that the vertical length is longer with larger breasts and that vertical length is needed to accommodate projection. The skin is not sutured to breast tissue, and the skin pucker is not sutured down to the chest wall; this would just delay resolution of the shape.

This patient had 255 g removed from her right breast and 195 g from her left breast. Liposuction volume was 400 cc. The vertical incisions measured 9 cm before closure and 9 cm after closure. The incisions were not cinched or gathered and the skin is not tacked down to either chest wall or breast parenchyma. The incisions were then covered with Micropore paper tape. Drains are rarely used. Patients are allowed to shower the next day, and the tape remains in place for 3 to 4 weeks.

Postoperative Care

Patients are placed in a noncompressing brassiere to provide support for about 2 weeks. They are not required to wear the brassiere, but most patients will wear some form of support for 2 to 3 weeks night and day. Patients are encouraged to shower the next day, and the paper tape forms a good cover and bandage. The tape is actually difficult to remove before 3 to 4 weeks, and it is easier to remove dry than in the shower.

Most patients understand that it takes about 1 to 2 weeks to get back to normal activities and 3 to 4 weeks to resume sporting activities. They can walk during the first week or so to remain fit, and they can walk uphill if they want to maintain an aerobic training level. They are advised to start with the stationary bicycle and then with time to progress to jogging. They can use lower-body weights initially, but they should hold off on upper-body weights for a few weeks. Patients are not restricted in their arm movement or in driving.

Problems

It is important to avoid any tension on the breast tissue or on the skin. Tension on the skin causes wound-healing problems, and tension on the breast parenchyma causes eventual loss of contour.

The most significant problem with a medial pedicle vertical breast reduction is the inability to make breasts as small as we would like. None of the breast reduction techniques can elevate the breast footprint and none of them can elevate the upper breast border. It can be difficult to achieve symmetry.

The most common reasons for revision are for correction of an inferior breast pucker, re-reduction, and correction of asymmetry. The most common complications are hematoma, seroma, infection, wound-healing problems, dehiscence, fat necrosis, and nipple necrosis.

Revisions

Correction of an Inferior Breast Pucker

It is not necessarily the case that puckers are more common with the vertical approach but they are easier to correct than the medial and lateral puckers that occur with an inverted-T procedure. Puckers can be prevented by adding a T, a J, or an L at the time of the initial surgery, but de Mey and colleagues noted that adding a T did not necessarily lower the revision rate. It is not always easy to design a T or to know exactly where to put it.

Puckers occur in many patients' breasts, but the pucker tends to disappear over time as it tucks in. Initially I thought it was best to correct puckers by adding a T incision, but that often adds two new dog-ears to chase. It is usually better to correct a pucker through a vertical skin incision and a horizontal fat excision. Most puckers are actually caused by excess subcutaneous tissue rather than by excess skin.

This patient had 300 g removed from the right breast and 290 g from the left breast. Her small puckers were corrected through small vertical elliptical skin excisions and larger horizontal fat excisions, with good results.

The same patient is seen at her 4-year follow-up.

Re-reduction

Re-reduction is not always straightforward. It is important not to remove too much skin. Wider tissue excision can be performed, especially laterally, as in the following patient. Liposuction is an important adjunct to a re-reduction. But often the vertical scar ends up too long, and the surgeon may need to add a J and an L or a T. Unfortunately, sometimes increased problems with dog-ears can be a nuisance.

This patient initially had a vertical breast reduction. She underwent re-reduction surgery, in which 403 g and 290 g were removed, and another 375 cc of liposuction. The vertical incision was too long, and a J and an L were added. It can be seen that this does not always solve the problem, because it adds a new lateral dog-ear to be chased.

Correction of Asymmetry

It is important to lower the new nipple position on the larger side when performing a breast reduction. This lower nipple position will be needed only partly because of the tension on the skin with the increased weight. But this is more of a problem with the vertical approach because closure of a wider inferior ellipse will push the ends further.

For this patient, the new nipple position should have been placed lower on the larger breast. Part of the problem is that the nipple has been pushed up; in addition, not enough inferior breast tissue was resected on the right side.

Complications

Hematoma

This patient came in 2 weeks after surgery with a hematoma. At that stage it was allowed to resolve on its own. This patient had had drains in place, and she was fine the morning after surgery, when the drains were removed. It is assumed that the actual removal of the drain led to some bleeding, which caused the hematoma. Since this instance, I have not used drains routinely.

It is important to know the vascular anatomy of the breast and to seek out any potential bleeders before closure. This is especially important in patients in whom tumescent infiltration has been used. The vessels may be in spasm, only to release later when the epinephrine effect has worn off.

The incidence of hematoma has only been about 1 in 400 patients.

Seroma

Seroma is probably fairly common. I have not aspirated or drained seromas routinely, and they seem to resolve uneventfully. We keep close contact with patients postoperatively, and rarely has a patient reported any spontaneous drainage. Unlike an abdominoplasty, in which a seroma does not have a path to drain, a breast seroma seems to resorb quite well.

Infection

Inevitably, infection will occasionally occur. I was able to reduce not only the incidence of infection in my patients but also the incidence of suture-spitting when I began to order 1 week of antibiotic therapy for all patients. The suture-spitting problem disappeared almost completely. Breasts have multiple ducts exposed to the environment, and I believe that they are not completely “clean.”

As reported by Bratzler and Houck, the National Surgical Infection Project now recommends giving only one intraoperative dose of antibiotics; unfortunately, when I did that, some suture-spitting and low-grade infection occurred, as seen above. The incidence of this problem seems to be reduced by using an antibacterial (triclosan-impregnated) suture (Monocryl Plus) and giving one intraoperative dose of an antibiotic agent. I think that many cases of suture-spitting were caused by low-grade infection.

Wound-Healing Problems

Although infection is one cause of wound-healing problems, I think that many areas of delayed healing are actually areas of too much tension. Wound-healing problems are common in inverted-T procedures at the T junction, and open sores and delayed healing are the most commonly reported problems with inverted-T breast reductions.

Now that I make certain that I avoid any constriction on the skin closure, the incidence of healing problems is extremely low. It is important to close the breast tissue pillars (to avoid fat necrosis) under very little tension and to close the skin (to avoid wound-healing problems) under very little tension.

Dehiscence

This type of wound dehiscence is uncommon and can result from either a low grade infection or more likely a suture failure. It is best not to resuture the area but to let it heal by secondary intention, as shown here.

Fat Necrosis

Fat necrosis tends to occur in the upper pole of the breast, just above the areola. This is most likely caused by some parasitic fat at the end of the pedicle that did not have an adequate blood supply. Although I have encountered a few patients with a firm mass in this area in the first few weeks to months after surgery, these masses have all resolved on their own without requiring any surgical intervention.

Fat necrosis can occur if large, constricting bites of tissue are taken to close the pillars. This is more likely to be a problem if the pillars are closed under tension.

More commonly, fat necrosis occurs in association with nipple necrosis when the blood supply to the pedicle fails.

Nipple Necrosis

Unfortunately, nipple necrosis can and does occur. This patient had partial nipple and areolar necrosis that healed very well without intervention. The first postoperative photograph shows the patient 4 weeks after surgery, the second at 6 weeks, and the third at 4 months. It is better to wait and see what results rather than debriding the tissue too early.

Outcomes

There is no question that all forms of breast reduction result in a significant improvement in back pain, neck pain, shoulder grooving, and even headaches. The rashes under the breasts can be reduced, and patients often report better exercise tolerance and psychological well-being. Patients often concentrate preoperatively on the symptoms, but postoperatively they concentrate on the cosmetic appearance.

Results

This 59-year-old patient was 5 feet 4 inches tall, weighed 82 kg (180 pounds), and wore a 40 D brassiere. She had a medial pedicle vertical breast reduction in which 430 g was removed from her right breast and 530 g from her left breast. Another 525 cc of liposuction was performed mainly in the lateral chest wall, preaxillary areas, and just above the inframammary fold. She is shown at her 1-year follow-up. The extra preoperative markings were done only for study purposes, and these measurements showed at 1 year postoperatively that the nipple position stayed at the same distance from the suprasternal notch as it was measured to be preoperatively (23 cm). The vertical scars measured 8 and 7 cm, respectively, and the inframammary fold was raised slightly.

This 38-year-old patient was 5 feet 9 inches tall, weighed 79 kg (175 pounds), and wore a 38 D brassiere. She had a medial pedicle vertical breast reduction in which 300 g was removed from the right breast and 320 g from the left breast. Another 300 cc of liposuction was performed in the lateral chest wall, preaxillary areas, and above the inframammary fold. She is shown at her 1-year follow-up.

This patient had a medial pedicle vertical breast reduction in which 800 g was removed from her right breast and 645 g from her left breast. She had an additional 325 cc of liposuction performed in the lateral chest wall and above the inframammary fold. She is shown 9 months after surgery.

This woman had a medial pedicle vertical breast reduction in which 350 g was removed from the right breast and 325 g from the left breast. Another 200 cc of liposuction was performed in the lateral chest wall and above the inframammary fold.

Clinical Caveats

Surgeons should understand the concept of low-breasted and high-breasted.

The medial pedicle vertical breast reduction is not about the scars; it is about the concepts.

A vertical or inverted-T skin resection pattern can be used.

The advantages are a long-lasting shape with good projection.

The surgeon should leave behind parenchyma in a Wise pattern and excise or liposuction all tissue beyond that pattern.

The vertical wedge resection is a key concept: it narrows the breast base, uses parenchymal excision and shaping to maintain the result, removes the heavy inferior pole, and does not rely on the skin as a brassiere.

What is removed in a breast reduction should be moved in a mastopexy.

Patient education is essential to a good result.

Annotated Bibliography

Asplund O, Davies DM. Vertical scar breast reduction with medial flap or glandular transposition of the nipple-areola. *Br J Plast Surg* 49:507-514, 1996.

Vertical scar breast reduction is a well-accepted technique that the authors believe improves the shape and projection of the breast and leaves no horizontal scars. Lassus and Lejour described superiorly based nipple flaps; the authors describe a medially based flap or glandular transposition of the nipple in small reductions.

Berthe JV, Massaut J, Greuse M, et al. The vertical mammoplasty: a reappraisal of the technique and its complications. *Plast Reconstr Surg* 111:2192-2199, 2003.

The authors modified their previous Lejour superior pedicle vertical scar mammoplasty technique by decreasing the skin undermining and avoiding liposuction in the breast. Primary skin excision was performed in the submammary fold at the end of the operation if the skin could not be puckered adequately. However, the technical modifications did not significantly change the rate of secondary scar and volume corrections, which were still necessary in 22% of the operated breasts. In large breasts, the addition of a horizontal scar at the end of the operation did not change the rate of secondary revision, which does compare favorably with the figures obtained with inverted-T superior pedicle mammoplasty.

Corduff N, Taylor GI. Subglandular breast reduction: the evolution of a minimal scar approach to breast reduction. *Plast Reconstr Surg* 113:175-184, 2004.

The authors describe a modification of the breast reduction procedure. By means of an inframammary incision, the breast is mobilized from the chest wall, and a “doughnut” anulus of breast tissue is removed from the undersurface of the gland. No skin is excised. The nipple-areola complex is left attached to a central core of breast tissue that receives its blood supply from the subdermal plexus of vessels. When the resulting defect is closed within the breast by strategically placed sutures, the base of the gland is narrowed, the breast is projected forward, and the circumareolar and vertical scars of other techniques are eliminated.

Hall-Findlay EJ. *Aesthetic Breast Surgery: Concepts & Techniques*. St Louis: Quality Medical Publishing, 2011.

A comprehensive text based on the author’s extensive experience in breast surgery, covering her approach to analysis and technique, which is simple and provides consistent results.

Hall-Findlay EJ. Pedicles in vertical reduction and mastopexy. *Clin Plast Surg* 20:379-391, 2002.

The author, who performed a standard inferior pedicle Wise pattern technique for the first 11 years of her practice and has now used variations of the vertical technique, found that the medial pedicle gives the best breast reduction results in her hands. A lateral pedicle is used for mastopexies so that the inferior and lateral tissue can be rotated up under the areola. When faced with a re-reduction of a previous inferior pedicle, the vertical technique can still be used, and an adaptation of the inferior pedicle can be very acceptable.

Hall-Findlay EJ. A simplified vertical reduction mammoplasty: shortening the learning curve. *Plast Reconstr Surg* 104:748-759; discussion 760-763, 1999.

The author describes modifications to the standard Lejour vertical reduction mammoplasty that simplify the technique and make it more reliable and easier to perform. These modifications include using a medial (or lateral) dermoglandular pedicle, not undermining the skin, using liposuction only rarely to reduce breast volume, and not using pectoralis fascia sutures; the modified technique has been used in a series of 400 vertical breast reductions. In this series, scarring was reduced and the technique was easily learned and applied.

Hammond DC. Short scar periareolar inferior pedicle reduction (SPAIR) mammoplasty. *Plast Reconstr Surg* 103:890-901; discussion 902, 1999.

A method of breast reduction is presented that maintains the blood supply and innervation to the nipple-areola complex by means of an inferior pedicle, reduces the breast volume by removing tissue from the periphery of the breast, maintains breast shape with internal plication sutures, and limits the scar using a periareolar technique with a short inferior vertical-to-oblique extension.

Lassus C. A 30-year experience with vertical mammoplasty. *Plast Reconstr Surg* 97:373-380, 1996.

The author had previously used a vertical mammoplasty without a submammary scar for all breast reductions with a central wedge resection, an upper pedicle for the areola, no undermining, and a vertical scar. However, in large breasts, the inferior portion of the vertical scar showed below the submammary fold. Therefore he added a short horizontal scar, following the dogma of the time that the length of a vertical scar should not exceed 5.5 cm. However, he found that the horizontal scar moved upward. Convinced that it was possible to finish every mammoplasty with a vertical scar, he again modified the procedure to make the vertical scar stay above the inframammary fold in almost all patients. This has proved to be a safe, effective, and long-lasting procedure.

Marchac D, de Olarte G. Reduction mammoplasty and correction of ptosis with a short inframammary scar. *Plast Reconstr Surg* 69:45-55, 1982.

The main sequelae of mammoplasties are scars, particularly visible when they trespass the breast limits. If the new inframammary fold is located higher than the original, the horizontal limb of the T suture can be kept short and hidden beneath the breast. The glandular tissue is split vertically and overlapped for ptosis. For reduction, an inferior resection with medial or lateral remodeling is performed. The results are very satisfactory for ptosis and mild to moderate hypertrophy. High conical breasts with minimal scars are produced.

Palmer JH, Taylor GI. The vascular territories of the anterior chest wall. *Br J Plast Surg* 39:287-299, 1986.

Through a series of fresh cadaver injection, dissection, and radiographic studies, the authors defined the vascular architecture of the anterior chest wall and correlated it to the findings of previous writers in this area. Their findings confirmed that the dominant supply to this region is from the internal thoracic artery, which interconnects in all layers with the posterior intercostals, the lateral thoracic, acromiothoracic, and transverse cervical arteries.

Schlenz I, Kuzbari R, Gruber H, Holle J. The sensitivity of the nipple-areola complex: an anatomic study. *Plast Reconstr Surg* 105:905-909, 2000.

Although preservation of the sensitivity of the nipple and areola is an important goal in breast surgery, only scant and contradictory information about the course and distribution of the supplying nerves has been found in the literature. The authors dissected 28 female cadaver breasts and found that the nipple and areola were always innervated by the lateral and anterior cutaneous branches of the third, fourth, and fifth intercostal nerves. Their findings suggest that the nerves innervating the nipple and areola are best protected if resections at the base of the breast and skin incisions at the medial areolar border are avoided.

Spector JA, Kleinerman R, Culliford AT IV, et al. The vertical reduction mammoplasty: a prospective analysis of patient outcomes. *Plast Reconstr Surg* 117:374-381; discussion 382-383, 2006.

Although breast reductions based on a Wise pattern incision remain common, patient and surgeon dissatisfaction with this procedure because of unsightly scars and long-term bottoming out of the breast prompted a search for alternative methods of breast reduction. The authors studied patient outcomes after vertical reduction mammoplasty using prospectively collected data from questionnaires. The authors found that vertical reduction mammoplasty resulted in significant improvement in all quality-of-life factors analyzed, including problems in buying clothes and brassieres, and difficulty in playing sports and running.

Würinger E, Mader N, Posch E, Holle J. Nerve and vessel supplying ligamentous suspension of the mammary gland. *Plast Reconstr Surg* 101:1486-1493, 1998.

The authors first described anatomic findings (from 28 breast specimens of female cadavers) showing a thin, horizontal, fibrous septum originating from the pectoral fascia along the level of the fifth rib, heading toward the nipple. This fibrous septum lies between a cranial and a caudal vascular network, and being mesentery-like, is responsible for the supply of the nipple areola complex. The cranial vascular sheet is supplied by the thoracoacromial artery and a branch of the lateral thoracic artery, whereas the caudal sheet is supplied by perforating branches from anastomoses of intercostal arteries. The fibrous septum is also a guiding structure for the main supplying nerve of the nipple. Knowledge of this structure is of value and relevance in clinical applications.

CHAPTER 69

Breast Reduction: *The Lateral Pedicle Technique*

MOUSTAPHA HAMDI, ANNE DANCEY

The multitude of techniques described for reduction mammoplasty pays testament to the lack of consistent results across all patient groups. Good and bad results are often attributed to each specific pedicle, and, as with all surgical procedures, it is this dissatisfaction that drives the pursuit of new and improved techniques. However, it is difficult to assign primary responsibility for complications or unsatisfactory results solely to a certain pedicle type. The global outcome in breast reduction can be attributed to many factors, including skin quality, the patient's age and expectations, the degree of ptosis, and the surgeon's experience. Although a variety of technical refinements have been described over the decades, each breast reduction procedure addresses the following essential elements:

- Preservation of nipple-areola complex blood and nerve supply
- Removal of excess parenchyma
- Excision of redundant skin
- Reshaping of the breast parenchyma
- Redraping of the skin

The vogue has been to create a vertical scar, the superior pedicle technique popularized by Lejour. However, despite good results in the hands of many experienced surgeons, there have been numerous problems with this technique, mainly related to the steep learning curve associated with the method. Nevertheless, the vertical scar mammoplasty remains popular with many surgeons because it provides long-standing aesthetic results with minimal scars. We feel that it is important to consider the vertical technique as a concept rather than as a scar with a specific pedicle. Breast shaping and remodeling are the most important elements of this technique, and they can be modified according to an individual patient's needs.

Skoog is credited with being the first to describe the use of a lateral dermal pedicle breast reduction in 1963. In 1999 Hall-Findlay reported using a lateral or medial dermoglandular pedicle combined with a vertical scar. This produces minimal scarring, and the concept of pedicle rotation avoids kinking of the pedicle and the venous congestion sometimes encountered with the superior pedicle. Hall-Findlay pointed out that there should be no undermining of the pedicle to ensure continuity with the chest wall and maximization of perfusion. This technique was further described by Cárdenas-Camarena and Vergara. Many surgeons still detach the lateral dermal pedicle from the chest wall and maintain a thickness of approximately 2 to 3 cm. Thus resection of glandular tissue occurs in a plane dorsal to the pedicle itself, as well as in the remaining quadrants of the breast. This considerably limits perfusion of the pedicle.

Würinger described a horizontal septum traversing the breast that carries an identifiable neurovascular supply to the nipple-areola complex. The sagittal section of the breast above shows the horizontal septum described by Würinger. With knowledge of functional three-dimensional breast anatomy constantly evolving, we have further modified the previously described techniques to optimize the vascularity of the breast and innervation of the nipple-areola complex. We have called this a *septum-based lateral mammaplasty* (SLM) and consider it to be an evolution of the centro-lateral glandular pedicle. It is this improved vascularization of the nipple-areola complex that is responsible for a significant decrease in early and late postoperative complications in our hands.

Our lateral glandular technique maintains a column of parenchyma between the pectoralis major muscle and the nipple-areola complex at the level of Würinger's septum. Thus continuity is maintained not only with the lateral breast pillar, but also with the chest wall itself, resulting in maximum preservation of perforating vessels.

Preserving the ability to lactate is often a fundamental prerequisite for women of reproductive age who intend to undergo a reduction mammoplasty procedure. It is known that sculpture of the pedicle during mammoplasty can influence breast-feeding potential, and therefore it is important to maintain as much continuity as possible between the remaining glandular tissue and the nipple-areola complex. Although to date we have no definitive data on postoperative breast-feeding, we intuitively feel that the SLM procedure retains maximum glandular continuity to maximize the chances of lactating.

Indications and Contraindications

The SLM reduces the infralateral and central parts of the breast, while the nipple-areola complex is centered on the horizontal septum via a lateral pedicle. The choice of pedicle depends on different factors, such as the degree of hypertrophy, the position of the nipple-areola complex, lateral fullness, and the age of the patient. The key to achieving an acceptable result in reduction mammoplasty is flexibility in the choice of pedicle and skin resection. No single procedure can be prescriptive; the surgeon must be able to choose the most appropriate procedure for each patient. In our experience, small reductions or mastopexies are often more suited to the superior pedicle technique.

We think that the SLM is best suited to younger patients, in whom it is paramount to achieve maximum nipple-areola complex sensitivity, continuity of the nipple-areola complex and glandular tissue for breast-feeding, and good projection of the breast mound. By definition, any lateral pedicle technique limits resection from the lateral pillar and axillary areas. This persistent lateral fullness can be a drawback, particularly in obese patients with excess axillary fat in addition to the macromastia. Basing the lateral pedicle over Würinger's septum ensures optimal vascularization of the nipple-areola complex and enables the surgeon to remove more tissue laterally than would be possible with standard lateral pedicle techniques. However, even with this additional perfusion, we recommend a septum-based medial pedicle mammoplasty (SMM) in patients with extreme lateral fullness.

Having a dual blood supply, the lateral pedicle (lateral thoracic artery) and the septum (intercostal arteries), makes nipple-areola vascularization more robust. Therefore the SLM technique is widely indicated for patients with macromastia or major breast ptosis. The transverse circumference of the breast does not increase dramatically with macromastia, in contrast to the vertical circumference. Thus a laterally based technique is likely to have a shorter pedicle length than its superior or inferior counterpart. To date, the senior author (M.H.) has performed resections of up to 2100 g per side with no compromise of nipple perfusion. Thus we have no specific upper resection weight limit, although in cases of extreme gigantomastia, a free nipple graft procedure may need to be considered.

The choice of skin closure pattern is based on the patient’s individual characteristics. This can be better determined perioperatively than during preoperative marking. In general, the vertical scar mammoplasty is selected for young patients (less than 30 years of age), for those with dark skin, or for patients who have nipple-to-sternal notch distances of less than 30 cm with good skin quality. These patients would be expected to have adequate skin retraction and a good cosmetic result from a vertical scar. For older patients, or those with a nipple-to-sternal notch distance of more than 30 cm, an L- or J-shaped scar or a limited inverted-T is used. However, in patients at high risk for hypertrophic scarring, a vertical scar is advised, and the patient is told that a secondary revision procedure will be necessary. Patients who have poor skin quality with associated striae are best suited to an inverted-T procedure.

Although the excellent vascularity of the nipple-areola complex allows this technique to be performed in patients who smoke, we favor techniques that limit skin undermining with direct excision of excess skin. We have found that leeches are not a good option for a congested areola, and an extensive infection can occur, especially in patients with known risk factors. For inexperienced surgeons, we recommend converting any pedicle-based mammoplasty technique to a free nipple-areola complex procedure in high-risk situations, such as a combination of a very long pedicle (more than 15 cm) in patients who smoke or have other vascular or metabolic pathologic conditions.

Pertinent Anatomy

Würinger et al described a ligamentous suspension of the breast containing a horizontal septum that attaches the nipple-areola complex to the thoracic wall at the level of the fifth rib. The septum includes branches and perforators from the intercostal, thoracoacromial and lateral thoracic vessels, as well as the lateral branch of the fourth intercostal nerve. This horizontal fibrous septum is a thin lamina of dense connective tissue that traverses the breast from medial to lateral and extends to the center of the nipple. Thus it divides the gland, including the lactiferous ducts, into cranial and caudal segments. This separation of the glandular tissue is proportionally consistent in all patients, in that hypertrophy of breast tissue appears to occur mainly

in the cranial segment. A laterally based pedicle technique that has its foundation on Würinger's septum will therefore allow resection of the cranial parenchymal excess, thus permitting maximum reduction of the parenchyma while preserving sensation and vascularity. Würinger's description has confirmed the findings of other anatomic studies to further our knowledge of the nerve supply to the nipple-areola complex. The anterior ramus of the lateral branches of the fourth intercostal nerve can take a superficial or deep course toward the nipple-areola complex. In the deeper variation, the nerve runs on the serratus and pectoralis major fascia before penetrating the breast parenchyma after 3 to 5 cm to run obliquely toward the nipple-areola complex. These findings were in accordance with a more recent study by Schlenz and colleagues, who also found that the lateral cutaneous branch of the fourth intercostal nerve supplied the nipple in 93% of breasts by following a deep retromammary course. In the remaining 7%, the anterior cutaneous branches of the third, fourth, and fifth intercostal nerves took a superficial course in the subcutaneous tissue. Thus to ensure that sensation is maintained, it is necessary to include the entire parenchyma surrounding the nerve. In the 2 to 3 cm thick pedicle described in traditional lateral pedicle techniques, sensation will only be preserved in the superficial nerve variant, leaving a percentage of patients with a sensory deficit.

Preoperative Assessment

History

The symptoms of female breast hypertrophy are often related to muscular discomfort. Patients frequently report back pain, neck pain, shoulder discomfort, and occasionally headaches. They often develop poor posture to compensate for the excessive breast weight. Poor hygiene in the submammary crease leads to irritation, rashes, and even skin infections. Shoulder grooves develop over time from the pressure exerted by brassiere straps. However, if the patient does not wear a brassiere, activities and even sleep may be difficult. The excessive breast weight often prevents a woman from participating comfortably in sports and wearing any form of revealing clothing. Typically, once this affects the patient's activities of daily living, she will seek medical attention.

In addition to gathering details on the presenting complaint, it is important to obtain a thorough medical history that specifically includes baseline information about breast cancer risk factors, the patient's menstrual history, and reproductive plans. At this stage it is useful to ask what size breasts she is hoping to achieve.

Physical Examination

Physical examination confirms the diagnosis of breast hypertrophy and attempts to rule out the possibility of breast cancer. It is essential to note the patient's skin type, striae, and any evidence of keloids or hypertrophic scarring from previous surgery or injury. This will affect decisions on the skin closure pattern. A record should be made of the patient's height, weight, and BMI.

An aesthetic examination of the breasts is typically performed with the patient sitting up or standing with her arms at her sides. Brassiere-strap grooves are assessed for depth and skin breakdown. Intertrigo is assessed by lifting each breast and closely examining the skin for breakdown and rashes. A circumferential evaluation of the muscular and bony thorax is essential. The vertical alignment of the thorax, asymmetry, or differences in shoulder position or muscle mass are noted. The two breasts and their relationship to the chest wall are compared to define any breast asymmetry at an early stage. Excess lateral breast tissue with a poorly defined lateral breast border is particularly noted, because this may disqualify the patient for an SLM. The relative volume and shape of the breasts are compared and recorded. Nipple-to-sternal notch and nipple-to-midline are measured and recorded. The degree of ptosis is assessed from the position of the nipple-areola complex in relation to the rest of the glandular tissue and the inframammary fold.

The breast examination is then repeated with the patient in the recumbent position with her arms by her sides and then elevated over her head. The breasts are assessed for any lumps, masses, scars, skin dimpling, or nipple discharge. Preoperative photographs are taken to document mammary hypertrophy to complete the physical examination.

Recommendations

The consultation includes a discussion of breast size, a review of the patient's expectations, and reinforcement of realistic goals for surgical treatment.

Preoperative Planning

Precise marking is the key to obtaining the desired aesthetic result with optimal breast symmetry. The breasts are marked on the day of surgery with the patient standing. The midline, inframammary fold, and meridian of the breast are outlined. The meridian is best marked by hanging a tape measure around the patient's neck and letting it drop toward the nipples. The nipple distance from the suprasternal notch is then measured and marked. Point *B* is the future position of the nipple. The distance between the points are as follows: *A* to *B* = 2 cm; *C* to *G* = *D* to *G'* = 6 cm; and *H* to *I* = 2 to 4 cm.

The proposed new nipple position is marked with the two-finger maneuver—placing two fingers in the inframammary fold and projecting this onto the skin (*left, arrow*). In the second photo (*right*), one finger is in the inframammary fold and the second finger would be where the tip of the marker is shown. However, the nipple is lowered 1 to 2 cm more than its position, as determined by the two-finger maneuver. This results in a new position at a horizontal line drawn from the lateral fold of the breast at the anterior line of the axilla toward the breast meridian (*left, arrow*). This ensures that the nipple position will not be too high, since it will be expected to rise by a certain degree when the pillars are approximated.

The vertical pillars are marked by rotating the breast superomedially and superolaterally to extrapolate the lines, as described by Lejour.

The mosque-shaped pattern of the areola, which varies from 14 to 20 cm in length, is adjustable to suit the size of the breast, the nipple distance from the sternal notch, and the new nipple position. The width of the mosque-shaped periareolar design, which is between 4 and 10 cm, should be larger for a greater resection and should also leave enough space for the pedicle to settle without compression.

The vertical, lateral, and medial lines are then connected in a curve to the periareolar line.

The medial line is marked first and can be transferred to the contralateral breast by pushing both breasts to each other (mirror effect), as shown. The medial limb has to be identical on both breasts to achieve good symmetry. The lateral limb position outlines the central segment of parenchyma and skin to be excised, which will determine the size of the reduced breast. The position of the lateral limb allows adjustment for any asymmetry between the two breasts. The vertical pillars are joined centrally at a level approximately 2 to 4 cm above the inframammary fold. The lateral pedicle is then marked with a 6 to 8 cm base.

The base of the pedicle is marked to be three quarters in the lateral vertical limb and one quarter as the opening of the areola, respectively. The final skin closure decision will be made while the patient is on the operating table, with the aid of a tailor-tacking technique.

The procedure is performed with the patient supine and under general anesthesia. The operating table should have a break to permit flexion to the sitting position; the patient's arms are held securely adducted to the side. The incision lines and base of the breast are infiltrated with 40 ml of 1% lidocaine and 1:200,000 epinephrine, diluted with 40 ml of normal saline solution. The pedicle itself should not be infiltrated to ensure that perfusion is not compromised.

Operative Sequence

The operative sequence can be summarized as follows:

1. A laterally based pedicle is developed located over Würinger's septum.
2. A two-part gland resection is divided into a crescentoid resection caudal to the septum, and a larger C-shaped resection is done cranial to the septum, around the pedicle.
3. Breast pillars are sutured in the midline and to the pectoralis fascia.
4. The skin is closed with minimal undermining in a fashion determined peri-operatively (tailor-tacking technique).

5. The lateral pedicle is deepithelialized and the inferior breast skin is undermined.

6. A C-shaped resection of the gland is done caudal to the septum.

7. The medial and cranial skin and gland are incised and the septum is dissected. The arrow (*left*) indicates an intercostal perforator vessel within the septum.

8. A C-shaped gland resection is done around the lateral septum-based pedicle.

9. The septum-based lateral pedicle is rotated upward.

10. The areola is closed using an interlocking suture technique.

11. The lateral pillar is fixed onto the pectoral fascia.

12. The skin is closed according to the technique described in number 3, p. 2501.

Operative Technique

69-1 Septum-based
lateral mammoplasty

The operative technique is as follows:

1. *Pedicle deepithelialization and skin incision:* All preoperative markings are checked to ensure that important landmarks have not been erased during patient preparation. The nipple-areola complex is marked with a 45 mm diameter areolar ring with no tension. Deepithelialization is performed on top of the glandular pedicle to the lateral vertical incision, leaving a 1.5 cm cuff of dermis around the areola. Skin incisions are completed with a scalpel.
2. *Pedicle dissection and glandular resection:* In preparing the inferior horizontal resection, the inferior pole of the breast skin is undermined, starting from the inferior limit of each vertical line (6 cm long) to 1 to 2 cm above the inframammary fold. The skin flap thickness is similar to that of the skin after a mastectomy. The superficial fascia is incised and dissected over the gland 2 cm above the inframammary fold.

This fascia remains attached to the inframammary fold and can be used to suspend the fold in a higher position at the end of the procedure, if needed. The gland is incised along the medial pillar (between points D and G') to the level of the pectoralis fascia. This line is then extended cranially along the new areolar marking toward point E, which lies at the upper edge of the base of the pedicle. Digital dissection superiorly, medially, and inferiorly permits good visualisation of Würinger's septum. The surgeon is careful not to dis-

sect laterally and centrally to prevent inadvertent undermining of the pedicle. Würinger's septum can be held and palpated to allow resection of the breast parenchyma under direct vision from around the pedicle. It is important to ensure that dissection inferior to the pedicle is minimal to avoid damaging the neurovascular bundles in Würinger's septum. Having excised the appropriate amount of parenchyma, the weight is noted to aid in symmetrization, and the specimen is sent for histopathologic evaluation. Meticulous hemostasis is maintained.

The dermis of the pedicle is carefully incised at the base to allow better upward rotation. The base of the lateral pillar is rotated superomedially and secured with 1-0 Vicryl to the pectoralis fascia. This maneuver transposes the pedicle to the midline of the breast without tension. In the majority of cases no further fixation is required, but fixation can be performed superiorly to the pectoralis fascia if additional support is needed. The inframammary fold is suspended if necessary and fixed onto the pectoralis fascia with heavy stitches using the superficial fascia that was dissected at the beginning of the procedure.

3. *Skin closure:* Points C and D at the new 6 o'clock position on the periareolar incision are closed with a 3-0 absorbable suture, and the lateral and medial pillars are approximated with 1-0 Vicryl sutures. The periareolar incision is closed in three layers: (1) a 2-0 PDS interlocking suture as described by Hammond, at the level of the deep dermis, beginning at the 12 o'clock position with a well-buried knot, (2) minimal interrupted 4-0 Vicryl suture to

approximate the dermis in a tension-free manner and ensure appropriate skin eversion, and (3) subcuticular 4-0 Monocryl. Attention is now turned to closure of the vertical incisions with one of the following modifications:

Vertical scar: If a vertical closure is advocated, then the skin is undermined to a very limited degree to permit closure with a small amount of wrinkling. The deep dermis is approximated with interrupted figure-of-eight sutures using 3-0 Vicryl, and a 3-0 Monocryl subcuticular purse-string suture is placed at the inferior edge of the scar. These sutures shorten the length of the scar and avoid migration over the inframammary fold. In the event of inadequate wound edge apposition, some interrupted 6-0 nylon can be used to achieve satisfactory approximation.

L or J scar: The skin excess is moved laterally at the inferior edge of the vertical scar to avoid crossing the inframammary fold or extending the scar medially.

Inverted-T scar: If an inverted-T closure is required, this is designed at the end of the operation. The vertical scar is tailor-tacked with staples and a horizontal ellipse is designed to excise the dog-ear. Thus the horizontal component is as short as possible. The skin is closed in two layers with subcuticular 3-0 PDS in the deep dermis and a subcuticular 4-0 Monocryl.

4. *Liposuction:* Liposuction is performed in selected cases once the skin has been closed. Indications include persistent asymmetry, lateral fullness, and the need for improved definition of the inframammary fold.

Postoperative Care

Suction drains are placed bilaterally, ensuring that the drains are in the retroareolar area before closure to prevent a hematoma that could compromise pedicle perfusion. Dermabond tissue glue is placed over the sutured incision lines as a waterproof dressing. This enables the wounds to be left free of dressings for monitoring, sterility, and patient comfort. The drains are removed after 24 to 48 hours and the patient is discharged. Patients are instructed to wear a nonwire sports bra day and night for a month to ensure optimal breast shaping and support.

Problems and Complications

The postoperative complications we experienced in a consecutive series of 110 patients are shown in the table. Scar-related problems, namely wound dehiscence, were the most common complication, occurring in approximately 8% of patients. Other complications included hematoma, skin necrosis and infection and occurred with a

frequency of less than 1%. Despite the fact that we wanted to use vertical and any other short-scar techniques to minimize scarring, we feel strongly that this should not be at the expense of a high rate of wound dehiscence and scar revision. Thus we have developed an algorithmic approach to skin closure.

Postoperative Complications in 110 Patients

Complications (N = 194 breasts)	Number (%)
Wound dehiscence	15 (7.7)
Wound infection	2 (1.0)
Unilateral retroareolar hematoma	3 (1.5)
Unilateral partial areolar necrosis	1 (0.5)
Unilateral total areolar necrosis	1 (0.5)

Outcomes

We have shown in a prospective study that the septum-based lateral mammaplasty maintains the sensitivity of the nipple-areola complex from the immediate postoperative period and that all patients had normal sensation at a 6-month follow-up. We have also observed excellent stability of breast shape, with an improved conical profile of the breast mound and projection of the nipple. By ensuring that the glandular pedicle remains attached to the pectoralis muscle, we preserve the original strength of the connective tissue support, which includes the attachments of the superficial fascia and Cooper's ligaments. Resection of glandular tissue superior to the pedicle and repositioning of the pedicle in a more cranial position result in improved nipple projection.

The key to preserving breast-feeding potential after reduction mammaplasty is preparation of the pedicle, sparing as many lobules and connected lactiferous ducts as possible; we also strive to maintain adequate nipple-areola complex sensitivity. We have no firm data on the possibility of breast lactation using our technique. However, several previous studies have shown the lateral dermal pedicle to be superior to many other reduction techniques in terms of successful breast-feeding. We feel that our technique is superior to many of the lateral dermal pedicle methods, because it preserves an intact column of glandular tissue, thereby leaving the functional unit of the breast undisturbed. Intuitively, this, combined with the total preservation of sensation to the nipple-areola complex we have demonstrated, should lead to successful breast-feeding.

Results

This 29-year-old patient presented for breast reduction. She had F cup breasts with a 31 cm nipple-to-sternal notch distance. The nipple was elevated to a 32 cm nipple-to-sternal notch distance. Following our algorithm, a vertical scar was indicated in this case. The breast was reduced using the SLM technique to create D cup breasts, as requested by the patient. At the same time, a fibroadenoma was included within the gland resection of the left breast. The vertical scar is shown at 6 months post-operatively.

This 46-year-old woman requested moderate breast reduction (from a DD cup to a B or C). A vertical scar closure was indicated by her preoperative nipple-to-sternal notch distance of 30 cm. Gland resection was 376 g on the right and 266 on the left. She is shown 1 year postoperatively.

This 55-year-old woman with a BMI of 35 had major breast hypertrophy. The nipples were located 42 cm (right breast) and 40 cm (left breast) from the sternal notch. An SLM procedure with an extended inverted-T scar was done. The scar was extended over the midline to immediately correct the dog-ears caused by the asymmetry of the inframammary folds and to the previous midline abdominal scar. The amount of gland resection was 1400 g on the right breast and 950 g on the left breast. The results are shown 5 years postoperatively.

This 44-year-old woman had undergone a gastric bypass procedure and had lost 60 kg (132 pounds) when she presented for a breast reduction/mastopexy procedure. In this challenging case, the nipples were located at 35 cm (right breast) and 38 cm (left breast) from the sternal notch. The skin quality was extremely poor; therefore the SLM procedure was done with a conventional inverted-T scar. The amount of gland resection was 850 g (right breast) and 1130 g (left breast). Preoperative views show the septum of the right breast. The septum became extremely thin as a result of the long-term breast hypertrophy and ptosis. The perforator vessels and nerves could still be seen through the septum that was transilluminated with the surgical light. Early results are shown at 4 months postoperatively.

Concluding Thoughts

We feel that the septum-based lateral mammaplasty technique is safe and valuable for breast reduction. This procedure provides resection of a large amount of breast tissue without compromising the viability of the nipple-areola complex. The main advantages are maintaining nipple-areola sensitivity and a good aesthetic outcome. The technique is strongly recommended for young patients with large breasts.

Clinical Caveats

The lateral pedicle technique is best suited to younger patients with a well-defined lateral breast border and no excessive lateral fullness. An alternative pedicle should be considered for patients who do not meet these criteria.

The technique offers increased viability of the nipple-areola complex, preservation of sensation to the nipple-areola complex, reduced rate of wound complications, and increased potential for breast-feeding. In addition, the support of the glandular tissue behind the nipple-areola complex improves the conical projection of the breast and prevents flattening of the nipple-areola complex.

Preoperative marking should be done on the day of surgery and is the key to achieving the desired result. The medial vertical incisions should be symmetrical, and any necessary adjustments can be made with the lateral incisions. The nipple should be sited 1 to 2 cm below the inframammary fold.

The dissection of the pedicle centers around Würinger's horizontal septum, which includes branches and perforators from the intercostal, thoracoacromial, and lateral thoracic vessels, as well as the lateral branch of the fourth intercostal nerve.

A two-part gland resection is performed as a limited crescentoid resection caudal to the septum and a larger C-shaped resection cranial to the septum, around the pedicle.

The lateral pillar is sutured onto the pectoralis fascia, thereby ensuring that there is no tension on the pedicle.

The final decision regarding skin closure is made while the patient is on the operating table:

- A vertical scar is best suited to patients with nipple-to-sternal notch distances of less than 30 cm and good skin quality. However, the vertical scar may also be appropriate in patients at high risk of hypertrophic scarring, although there is a high incidence of secondary revisions.
- An L- or J-shaped scar is suitable for older patients or those with a nipple-to-sternal notch distance greater than 30 cm.
- The inverted-T scar is used in patients who have poor skin quality with associated striae.

Liposuction can be undertaken to give better symmetry, reduce lateral fullness, and create better definition of the inframammary fold.

Annotated Bibliography

Chiummariello S, Cigna E, Buccheri EM, et al. Breastfeeding after reduction mammoplasty using different techniques. *Aesthetic Plast Surg* 32:294-297, 2008.

The authors review breast-feeding ability after four different pedicle techniques of breast reduction used in their unit. Breast-feeding was defined as more than 3 weeks of lactation not requiring nutritional supplementation. Breast-feeding was successful in 60.7% of patients with a superior pedicle, 55.1% with a lateral pedicle, 48% with a medial pedicle, and 43.5% with an inferior pedicle. No description was given of the technique used or statistical analysis of results. The authors conclude that the ability to breast-feed is adequately preserved in techniques that spare the connections between the lobules and milk ducts and vital nipple-areola complex.

Hamdi M, Van Landuyt K, Tonnard P, Verpaele A, Monstrey S. Septum-based mammoplasty: a surgical technique based on Würlinger's septum for breast reduction. *Plast Reconstr Surg* 123:443-454, 2009.

This paper describes the septum-based mammoplasty with use of a medial or lateral pedicle technique, as indicated. An algorithmic approach is used for decision-making, particularly in relation to the pattern of skin closure. The authors' experience with a series of 110 consecutive patients over a period of 7 years is outlined. Resections ranged from 160 g to 1980 g, and the postoperative complication rate included 0.5% areolar necrosis, 7.7% limited wound dehiscence, 9% secondary scar revision. The technique is considered to be safe and demonstrates ease of pedicle shaping and breast remodelling in patients undergoing reduction mammoplasty.

Hamdi M, Vande Sijpe K, Van Landuyt K, Blondeel PN, Monstrey S. Evaluation of nipple-areola complex sensitivity after the latero-central glandular pedicle technique in breast reduction. *Br J Plast Surg* 56:360-364, 2003.

The authors record the sensitivity of the nipple-areola complex in 20 consecutive patients undergoing a septum based lateral pedicle technique. Measurements are made pre-operatively, at 2 weeks and 3 months post surgery using a variety of validated sensory measurements. Results show that at 2 weeks all patients had reduced sensitivity, but by 3 months pressure and vibration perception were the same as the preoperative measurements. Temperature recognition on the nipple remains impaired in 27.5% of patients at 3 months. They conclude that the latero-central pedicle preserves sensitivity of the nipple-areola complex in all patients.

Schlenz I, Kuzbari R, Gruber H, et al. The sensitivity of the nipple-areola complex: an anatomic study. *Plast Reconstr Surg* 105:905-909, 2000.

The authors dissected 28 female cadavers to record the nipple and areola innervation. The most constant innervation pattern was by the 4th lateral cutaneous branch (79%) and by the 3rd and 4th anterior cutaneous branches (57%). The anterior cutaneous branches took a superficial course within the subcutaneous tissue. The lateral cutaneous branches took a deep course within the pectoral fascia and reached the nipple from its posterior surface in 93 percent of the dissected breasts. In 7% of the dissected breasts, the lateral cutaneous branches took a superficial course within the subcutaneous fat and reached the nipple from the lateral side. The authors suggest that resections at the base of the breast and skin incisions at the medial areolar border are best avoided.

Würinger E, Mader N, Posch E, et al. Nerve and vessel supplying ligamentous suspension of the mammary gland. *Plast Reconstr Surg* 101:1486-1493, 1998.

This paper gives an anatomic description of a thin horizontal septum of dense connective tissue in the breast, based on the authors' findings for 28 breast specimens. This septum is the basis for the neurovascular supply to the nipple and contains branches of the lateral thoracic artery, the thoracoacromial artery and intercostal arteries. The nerve supply runs along the septum, either following a deep course from the lateral cutaneous branch of the 4th and 5th intercostal nerves, or a more superficial course from the anterior and lateral branches of the 2nd to 4th intercostal nerves.

CHAPTER 70

Short-Scar Mammoplasty With a Pectoralis Loop

RUTH MARIA GRAF,
ANDRÉ RICARDO DALL'OGGIO TOLAZZI,
MARIA CECÍLIA CLOSS ONO, THOMAS M. BIGGS

Breast surgery is ever evolving; the great advances of Wise, Pitanguy, Lassus, Lejour, Benelli, and others have given us techniques that not only simplify the operative plan for mammoplasty but also produce a shorter scar and a more aesthetic breast. In this chapter we will describe the short-scar mammoplasty with a pectoralis loop, a maneuver designed to give a pleasing and long-lasting contour to the breast. This maneuver involves the use of a chest wall–based flap of breast tissue that is moved into the upper pole of the breast and held in place by a loop of pectoral muscle, under which it is passed. The technique can be used with standard inverted-T incisions, vertical incisions with short transverse components, L-shaped incisions, or pure vertical incisions. Our choice, and the maneuver described in this chapter, is a vertical incision, with redundant skin removed from around the areola after excision of a vertical ellipse, and closure with a round block suture. If breast reduction is necessary, it can easily be carried out by removing the desired amount of tissue from the base and central part of the breast. A wide range of parenchymal reduction procedures can be performed.

Indications and Contraindications

It is possible to use this combination of techniques for mastopexy only, when there is no excess breast tissue to be removed, or for breast reduction, when resection of excess breast tissue is done in the columns or base of the breast, after the thoracic wall flap is fixed. With this technique we found that we removed less breast tissue than with other techniques that do not use the chest wall–based flap, and the breasts have a narrower base. In our experience, the average amount of breast tissue resected was 250 to 500 g, less than in other techniques we have used without the thoracic flap.

This technique is ideally indicated for mild and moderate cases of breast ptosis and hypertrophy, where less skin compensation is necessary. Significant hypertrophy and severe ptosis constitute relative contraindications to vertical mammoplasty. We prefer to use a short inverted-T incision in these cases to excise more skin and reduce skin compensation. This patient has significant breast ptosis, and the breast has been marked for the inverted-T pattern of skin resection.

Pertinent Anatomy

The mammary gland is anchored to the pectoralis major fascia by the suspensory ligaments (Cooper's ligaments), which help to maintain the shape of the nonoperated breast.

The breast is innervated by the second to sixth intercostal nerves. Lateral innervation is predominantly from the anterior rami of the lateral cutaneous branches of the third through sixth intercostal nerves. Medial innervation arises from the anterior cutaneous branches of the second through sixth intercostal nerves. The nerve supply to the nipple is from the third, fourth, and fifth anterior and lateral cutaneous nerves. The lateral cutaneous branch of the fourth intercostal nerve, which is considered to be the most important, innervates the nipple with two branches. The superficial branch passes up through the superficial parenchyma; the deep branch passes inferolaterally on the pectoralis major fascia before coursing up into the areola. This fact might give one pause in considering techniques that rely heavily on inferolateral resection of the gland.

The blood supply to the mammary gland is from multiple sources, including the internal mammary perforators (most notably the second to fifth perforators), the thoracoacromial artery, the artery to the serratus anterior, the lateral thoracic artery, and the terminal branches of the third to eighth intercostal arteries. One important aspect, first described in 1998 by Würinger et al, is the concept of a mesentery-like fibrous septum that runs through the breast at the level of the fifth rib and contains perforator vessels responsible for the blood supply of the nipple-areola complex. We apply this concept when thinking about the dissection of a chest wall-based flap, which is important for achieving an ideal breast shape.

Preoperative Assessment

Each patient must be evaluated for the amount of breast parenchyma, the amount and quality of excess skin, and the scars that are acceptable to the patient. Local breast examination is performed to exclude masses, and any suspicious lesion should be fully investigated before surgery. It is advisable to obtain preoperative mammograms in all patients older than 30 years of age, and breast ultrasonography in younger patients.

Preoperative Planning

Markings are done with the patient in the upright position. The midline (*M*) is drawn from the suprasternal notch to the xyphoid process, breast meridians are marked from a point 5 cm lateral to the suprasternal notch over the clavicle to the nipple-areola complex. On the breast meridian line, point *A* is marked about 17 to 20 cm from the clavicle, at the top of the areola, and point *D* about 2 to 4 cm above the inframammary fold, depending on breast size. If the patient has significant hypertrophy or severe ptosis, point *D* should be marked higher, up to 4 cm above the inframammary fold. This leaves skin and subcutaneous tissue of the lower breast pole as part of the thoracic wall, with a higher new inframammary fold.

The breast is then gently displaced laterally (the technique described by Lejour) and a medial line is drawn connecting point *A* to point *D*. Similarly, a lateral line is drawn with the breast displaced medially. The tension resulting from these displacements should be firm enough to allow adequate skin resection, but not so tense as to create difficulty with closure. This distance varies, depending on the size of the breast. The

medial and lateral lines, points *B* and *C*, respectively, are marked about 5 to 8 cm above point *D*. A gently curved line is drawn from point *A* to point *B*, and again from point *A* to point *C*. Line *AB* should never be closer than 9 cm to the midline, and line *AC* never less than 10 cm to the anterior axillary fold.

The variation in distances of point *D* to the inframammary fold and vertical lines *BD* and *CD* allows the surgeon the latitude to make adjustments, depending on the size of the breast. The larger the breast, the greater these distances, but never exceeding 4 and 8 cm, respectively. Points *B* and *C* are marked slightly closer to each other so they can be closed with less tension.

Operative Technique

The patient is placed supine on the operating table and is prepared and draped. General or epidural anesthesia is induced (in some cases local anesthesia may be used), and the marked areas are infiltrated subdermally (except superior to the areola) with normal saline–epinephrine solution (1:100,000). The area of skin demarcated by *AB*, *AC*, *BD*, and *CD* is deepithelialized by a Schwartzman maneuver, leaving the nipple-areola complex (4.5 to 5.0 cm in diameter) in place. To start creating the chest wall–based flap, the dermis is incised along the lines *BD* and *CD*, as well as *BC*, passing 1 cm below the nipple-areola complex.

70-1 Vertical
mammoplasty

Along the vertical lines, the incision is beveled inward for 1 to 2 cm to preserve tissue on the medial and lateral pillars for later closure. The incisions continue inward and away from the flap so that the base is broad. This dissection is carried to the chest wall, with a minimal amount of subcutaneous tissue being left on the skin as dissection is carried to the inframammary fold.

After this dissection has been completed laterally and medially, a large hook is placed in the nipple-areola complex to lift the breast straight up and help with the dissection of the breast tissue from point *B* to *C* down to the pectoral fascia. Great care must be taken at this point not to undercut the flap. The flap is now mobile and based on vessels from the fifth and sixth intercostal spaces as a perforator flap. It is very important that the flap is unrestrained; otherwise, continuous dissection should be extended to the pectoral fascia to better release it. This freely mobile, totally chest wall-based flap is made up of the tissue that in other procedures bottoms out, but in this procedure it is being transposed into the upper pole, where it will be permanently fixed.

The breast tissue is retracted upward and cephalad and dissected off the pectoral fascia up to the second intercostal space, creating a space in the upper pole of the breast into which the flap will be fixed.

Markings

Dissection

Closure

A strip of pectoral muscle approximately 8 to 10 cm long and 1.5 to 2.0 cm wide is marked with methylene blue. The caudal or inferior line is marked at the cephalad end of the flap base. This muscle strip is elevated, incorporating no more than half of

the muscle thickness (the posterior fascia of the muscle is not violated), and the donor site is close with 2-0 nylon. This loop will be used to help hold the flap in the upper pole of the breast.

The mammary flap is then passed under the pectoral loop into the space created in the upper pole of the breast. It is very important that all dermal elements on the flap be completely passed under this loop.

A running suture of 2-0 nylon, starting laterally and finishing medially, is placed to fix the breast tissue of the flap to the pectoral fascia. The dermis of the flap is then sutured to the pectoral flap, superiorly only.

If after passing the flap under the loop there seems to be excess tension on the loop causing pressure on the flap, the loop can be released laterally, since medial dissection could disrupt the origin of the muscle.

With the flap in the correct position, the breast tissue excess can be resected. Equalization of breast tissue pillars is shown. Breast reduction is performed, depending on breast size and the desire of the patient. Most of the tissue is removed as a central inverted-V excision pattern to narrow the base of the breast, and, if necessary, from the base to reduce breast projection. One should avoid overreducing the medial part of the breast—the tissue under the nipple-areola complex—to produce more projection of the complex. Significant reductions with this technique (vertical incision and circumvertical closure) remove about 800 to 1000 g, including the liposuction in the lateral aspect of the breast, which is in average 300 cc of fat. The chest wall-based flap can be used in any breast size.

After reduction of excess breast tissue, and with the hook still holding the breast straight up, one interrupted stitch of 2-0 nylon is placed from the superior part of the breast parenchyma to the pectoralis muscle, just superior to the chest wall-based flap, at the level of the second intercostal space to aid in upper pole definition.

The pillars are then closed with 2-0 nylon in several layers. It is preferable to place the needle deeper laterally than medially to preserve more fullness medially. Closure of mammary pillars and the deep dermis union of points *B* and *C* are shown.

Deep dermis of the vertical wound is sutured, starting with subareolar points *B* and *C*. To reduce the outer circumference and wound tension, and to compensate the periareolar skin around the areola, a round block suture is made all the way around the periareolar skin with 3-0 colorless nylon. Eight cardinal points are marked in the outer and inner circumferences to spread the periareolar skin uniformly around the areola. The running suture passes through the deep dermis of the outer skin and the areolar deep tissue. In the external skin the suture follows the markings, taking a large bite of tissue; in the areola the suture is passed between the markings, taking a small amount of tissue. Tensioning the suture reduces the outer circumference down to the desired diameter for the nipple-areola complex (about 4.5 cm).

Starting from point *D*, the skin is closed with a subdermal interrupted suture of 3-0 Monocryl, anchoring the vertical wound on the deep pillars of tissue, so the vertical scar is kept at the same level as the new inframammary crease.

In patients with significant skin redundancy, it is possible to excise a small horizontal ellipse of skin in the new inframammary fold, ending with a short inverted-T scar. This can better adjust the skin envelope without jeopardizing the youthful breast shape achieved with vertical principles associated with chest wall-based flap. A running intradermic suture with 4-0 Monocryl finally closes the skin. No drains are used. An excision of a horizontal ellipse of skin is shown above, which ends with a short inverted-T scar in selected cases.

Postoperative Care

A compressive, molding brassiere is recommended for 1 to 2 months to reduce postoperative swelling and tension on scars. It also helps to support the breasts while internal tissues are healing and until the final shape is more stable.

Massage and ultrasound therapy for lymphatic drainage are indicated from the second postoperative day, three sessions per week for the first postoperative month or two. Significant reduction in swelling and pain and increased comfort have been reported by patients who received these treatments.

Special care of scars is necessary to improve healing. A topical antibiotic ointment maintains local moisture and helps with cell migration to accelerate wound healing. After the first week, when all the wounds are healed, and for 2 to 3 months postoperatively, Micropore tapes are used over the scars to prevent stretching and widening them. Silicone gel or sheets can also be used to help prevent hypertrophic scars.

The patient is encouraged to walk the first day after surgery; driving and other physical activities can be resumed after 3 weeks.

Patients are closely followed in the postoperative period and are clinically evaluated at 5 to 7 days, 2 weeks, 1, 3, 6, and 12 months, and yearly thereafter. The patient's results are documented photographically at each follow-up visit.

Problems and Complications

The major drawback to this procedure is the length of time before the final result can be appreciated. The surgeon and patient must be patient while the skin retracts, wrinkles flatten, and the overcorrected breast, with its superior bulge and inferior flatness, evolves to an aesthetically pleasing contour.

Wound-healing problems such as dehiscence, widening, and irregularities are sometimes seen as a result of the vertical and periareolar skin-gathering suture. Eventually some skin redundancy remains in the new inframammary fold, which necessitates excision by a horizontal approach. Although this horizontal incision is small, it does add a horizontal component to the resulting scar. It is important not to elongate the scar out of medial and lateral limits of the breast to avoid hypertrophic scars.

Outcomes

Better and long-term upper pole fullness (second, third, and fourth costal rib) has been observed with the patient in the erect position. Breast shape and projection have been stable when the patient is lying supine. The areola maintains its upward projection, with little lateral tilting. Vertical and periareolar scars are usually of good quality, because there is less tension in the closure. Approximating the pillars and the round block suture reduces wound tension and improves the final scar. Narrowing the base of the breast is observed in all cases.

Results

The patient is seen preoperatively and 2 years postoperatively.

The patient is seen preoperatively and 1 year postoperatively.

The patient is seen preoperatively and 2 years postoperatively.

The patient is seen preoperatively and 3 years postoperatively.

The patient is seen preoperatively and 10 years postoperatively.

Concluding Thoughts

Long-term breast projection and upper pole fullness remain goals of mammaplasty. The chest wall–based mammary flap held by the pectoralis loop helps to achieve these goals and results in a youthful-looking breast. The flap can be performed in any kind of reduction mammaplasty or mastopexy. Short scars, such as those in the periareolar vertical technique, are good for mild and moderate breast hypertrophy and ptosis.

Clinical Caveats

The vertical principles associated with a chest wall–based flap held by a pectoralis strip promote better and long-lasting breast upper pole fullness with the patient in both upright and supine position. The areola remains in a good location and very little breast descent occurs, with no bottoming out.

The absence of a scar in the inframammary fold is a major advantage. The circumvertical scar does not cross the new inframammary crease and has a better quality because of the reduced skin tension, achieved through the round block suture and internal sutures of breast tissue.

A youthful appearance of the breast is achieved as a result of better projection and a narrower base.

CHAPTER 71

Alternative Approaches to Breast Reduction

ELIZABETH J. HALL-FINDLAY, FOAD NAHAI

Breast reduction can be immensely satisfying for both the patient and the surgeon. This is the only procedure that we perform on the female breast that treats symptoms. Outcome studies have repeatedly shown high patient satisfaction, along with significant improvement in back pain, neck pain, shoulder grooving, skin rashes, and even headaches. It is equally important to document the real improvement in self-esteem with improvement in posture, exercise tolerance, and psychological well-being.

Surgery is the only real option available for breast reduction. Medical treatment, such as hormone therapy, is not effective. Supportive brassieres can help to a relatively minor degree, because they transfer the discomfort to other areas, such as the shoulders.

The goals of breast reduction surgery are to reduce volume while achieving an aesthetically pleasing shape and maintaining breast function. For improved shape, the nipple-areola complex must be moved superiorly. Surgical approaches should preserve blood supply not only to the nipple and areola, but also to the remaining parenchyma and skin. Sensation and breast-feeding potential are also considered.

As famously stated by Sir Harold Gillies, much that we do in plastic surgery involves a battle between beauty and blood supply. Breast reduction is no different. Patients request improvement in symptoms and they are rarely disappointed. On the other hand, the rate of lawsuits for breast reduction is high, proving that aesthetics are just as important. Patients request the surgery for medical reasons, but they seek legal advice for the cosmetic result (see Chapter 8).

Evolution of Technique

Before 1900, attempts to reduce breast size were limited to volume reduction without much regard to nipple position or viability. In the first part of the twentieth century, multiple techniques were described to move the nipple-areola complex and to reduce bulk. To maintain viability, two-stage procedures were often recommended.

As time progressed, surgeons focused on better preservation of nipple and skin flap circulation and shape. Various pedicles and resection techniques were described, each with advantages and disadvantages.

The following principles of breast reduction became clearer with experience:

1. The dermoglandular pedicle is considered preferable for the nipple-areola complex to maintain blood supply, preserve sensation, and increase the potential for lactation. (At least, this is true in North America.)
2. Extensive skin undermining should be avoided to reduce problems of skin necrosis that were common in the Biesenberger type of procedure (which was the most popular mammaplasty procedure between 1930 and the 1980s).

In North America the inferior pedicle technique combined with an inverted-T closure proved most effective for accomplishing these principles. This method proved safe, reproducible, and relatively easy to teach. Minor wound-healing problems occurred at the T junction, but the technique provided relative safety for the nipple-areola complex. Sensation was good, and lactation was certainly possible in many patients. The trade-off of extensive scarring was undesirable but certainly thought to be justified. The boxy shape, along with lateral and medial dog-ears, was an issue that could not always be solved. The development of pseudoptosis or bottoming out with time was thought to be an inevitable consequence of gravity acting on skin with poor elasticity.

The inferior pedicle eventually became the workhorse of the inverted-T approach. McKissock's initial description of a vertical bipedicle was revolutionary at the time, but it was soon realized that either the superior or inferior pedicle alone was sufficient. One pedicle made inset of the nipple easier and thereby avoided some of the tension on the nipple-areola complex. Strombeck's horizontal bipedicle had similar problems. Skoog advocated a lateral or medial pedicle instead.

Many of the pedicles for the inverted-T procedure suffered because they had to be thinned and converted to a dermal pedicle to allow ease of inset. This approach was unfortunate because it reduced blood supply, innervation, and breast-feeding potential. Only the inferior and central pedicles were full thickness and stood the test of time. Some surgeons adopted the central mound technique, despite the skin undermining, because it had a good blood supply and was thought to provide better potential for lactation. Grading became a champion of either free nipple grafts or a superior pedicle combined with an inverted-T skin pattern.

On the other hand, Europeans and South Americans obtained good results with various types of vertical skin closure and circumareolar techniques. The circumareolar techniques proved difficult to reproduce and tended to flatten the breast, resulting in widening of the areolar scar and the areola itself. These procedures have been restricted to small reductions and mastopexies.

The vertical reduction mammoplasty techniques were slow to gain popularity in North America. The superior pedicle (as described by Lassus, Marchac and de Olarte, Lejour, Berthe, Nahai, and Hidalgo) can be difficult to inset and often requires aggressive thinning. Otherwise, the pedicle could be compressed by the excessive folding required.

Various other pedicles for the vertical approach have been described in an attempt to make the procedure easier and more applicable to larger breast reductions. American surgeons were initially intimidated by the odd shape at the end of the procedure and were nervous about leaving an inferior pucker that could take months to settle.

In U.S. surgical practices, patients with smaller breast reductions tend to be more critical of their results. Most surgeons continue to use the technique with which they are comfortable (inferior pedicle with inverted-T closure), especially to avoid potential lawsuits in a country that has become increasingly litigious. However, surgeons keep circling back to previously described techniques to combine the best aspects of the older methods with newer approaches that incorporate shorter scars.

Indications for and Advantages and Disadvantages of Various Techniques

Breast reduction techniques are sometimes divided arbitrarily into long- and short-scar techniques. Often the term *Wise pattern* is used to describe the inverted-T inferior pedicle technique, but care must be taken to separate the skin resection pattern from the pedicle design. Wise described only a skin resection pattern. It is not reasonable to compare one skin pattern using one pedicle with another skin pattern using a different pedicle.

Many surgeons who have now adopted the vertical skin resection pattern approach have stayed with it because of the improvement in the scarring, breast shape, and longevity of shape. However, it is not the skin pattern that makes the difference; it is the nature of the parenchymal resection and the pedicle design that resists gravity. Some surgeons add a short horizontal scar to remove redundant skin, but this approach is still different from most procedures that use an inverted-T skin pattern. It can be confusing, because people are often comparing apples with oranges.

Although the skin and dermis help shape the breast with the inverted-T designs, there is likely to be more bottoming out or pseudoptosis with time if the weight of the pedicle and the remaining breast are left inferiorly. Advantages of the so-called ver-

tical techniques should not be attributed to the skin pattern; rather, they result from the fact that the breast parenchyma is resected inferiorly and the pedicle weight is carried superiorly. Skin and dermis are elastic structures that adapt to stress; they are not particularly good at resisting deforming forces.

To properly evaluate the advantages and disadvantages of the different approaches to breast reduction, we must separate the approach to the nipple-areola complex from the skin and parenchymal resection patterns.

Skin Resection Patterns

Historically, one skin resection pattern is often associated with a particular pedicle, but the two should be considered separately. Most of the skin and parenchymal resection patterns can be combined with most of the pedicles. The final scar should reflect the pattern of skin resection chosen to deal with the excess skin once the breast shape has been established. The skin brassiere can no longer be relied on to shape or support the breast. How much breast tissue is removed, where it is removed from, and how the remaining tissue is brought together shapes the breast, not the skin.

Inverted-T Skin Resection Pattern

The inverted-T skin resection pattern has become the mainstay of breast reduction and usually is associated with the inferior pedicle. This approach relies on the skin brassiere to shape and hold the remaining breast parenchyma. With the advent of vertical techniques, it has become evident that it is not always necessary to remove all the skin above the inframammary fold. The inverted-T skin resection is best for patients with very large breasts or for massive-weight-loss patients who have a large amount of loose, inelastic skin.

Vertical Skin Resection Pattern

The vertical skin resection procedure has taken some time to gain wide acceptance. It is not for all patients, but it can be applied to a wide variety of breast sizes. Whereas inverted-T patterns rely on the skin to shape the breast, vertical patterns rely on the breast to shape the skin.

Initially the vertical skin resection was limited to smaller breast reductions, but now surgeons are using it for reductions up to 2000 g and above. Some surgeons prefer to use the vertical approach for the parenchymal resection because it cones the breast better than the inverted-T. For the larger reductions, they will add a short T or an L to remove the excess skin, but retain the shape advantages of the vertical approach. Berthe and colleagues showed that adding a T during the initial surgery did not change their revision rate. It can be difficult to know exactly where to place the T. The problem then becomes one of chasing lateral and medial dog-ears again.

Because vertical patterns are often associated with superiorly based pedicles and because the inverted-T usually is associated with an inferior pedicle, the vertical method may retain its shape longer, because it avoids the deleterious effects of gravity. The reduced incidence of bottoming out, or pseudoptosis, may be attributed to the nature of the parenchymal resection rather than the skin pattern. Several authors noted that the weight of the inferior pedicle stretches the skin and causes bottoming out with time. It is probably a combination of removing breast parenchyma inferiorly and not relying on the skin to hold the shape that has given the vertical pattern a better reputation for longevity. The illustration above compares the inverted-T and vertical skin resection patterns.

Lateral Skin Resection Pattern

Lateral skin and parenchymal resection patterns alone, as described by Dufourmentel and Mouly, result in medial displacement of the nipple-areola complex. This shape is unacceptable in larger reductions. When designed separately from the skin, parenchymal resection can achieve an acceptable result. The tissue is resected using various pedicles, and the skin excision is tapered laterally. Lateral skin resection avoids the unsightly medial inframammary scar that can occur with the inverted-T resection but still sometimes results in medial displacement of the breasts and an unattractive shape.

The B technique (Regnault) was a variation on the lateral resection. It used a superior pedicle and tapered the skin resection laterally, leaving a B-shaped scar. This method did not achieve general acceptance, because the design is somewhat complicated.

Circumareolar Skin Resection Pattern

Small breast reductions can be performed through a circumareolar skin excision where the “donut” is sutured to the “hole” during closure. Benelli has described a “round block” technique, but it has not achieved wide acceptance. With this technique the skin must be separated from the gland first so that there is minimal tension on the skin closure. A permanent suture is still required to prevent scar widening. This method can be applied to small reductions and mastopexies with minimal ptosis.

Sampaio Goés has used absorbable and permanent mesh to help hold the shape of the rearranged gland, but this mesh is not available in North America. Surgeons also have used dermis as a sling or support mechanism, but skin and dermis are well known for their elastic properties; they both stretch when placed under tension.

Pattern With No Vertical Scar

For a skin resection pattern that avoids the vertical scar, most surgeons use a form of broad-based inferior pedicle. This works well for very large breast reductions, but even with parenchymal rearrangement, the breasts tend to be flattened and lack upper pole fullness. Many surgeons believe that the vertical scar is less of a problem aesthetically than the long scar in the inframammary fold. The vertical incision may be more visible in frontal view, but it is less prone to develop hypertrophic wide scars than the inframammary fold incision.

Liposuction-Only

Liposuction alone can be an effective technique, but it relies on skin elasticity and retraction. The nipple can rise to a higher position if liposuction is performed above the areola, but this can lead to loss of upper pole fullness. The breasts tend to be flatter and have residual ptosis.

Liposuction has a lower risk of complications. Nipple necrosis is less likely, and sensation and breast-feeding potential are more likely to be preserved. The procedure is more easily performed in a fatty breast, such as the already ptotic perimenopausal breast. This procedure does not work well in the most ideal indication: a teenager who is of normal body weight. Teens can have thick, fibrous, glandular breasts with minimal fat. This approach has been advocated for medically compromised patients, because it is a relatively fast procedure and some consider it less invasive.

Blood Supply to the Nipple-Areola Complex

Pedicles can have many different variations, but they are generally classified as horizontal, vertical, inferior, superior, central, lateral, and medial.

Horizontal Bipedicle

The horizontal bipedicle (Strombeck) combined a laterally based circulation to the areola with a medially based circulation. A dermal pedicle was usually sufficient but often caused nipple retraction. The more robust dermoglandular pedicle was also more difficult to mobilize and inset. This approach fell out of favor because of these difficulties.

Vertical Bipedicle

The vertical bipedicle (McKissock) offered a significant improvement because it provided sufficient circulation to the nipple and was not as difficult to inset. It remained the mainstay of breast-reduction surgery in North America in the 1970s but has since been abandoned by most surgeons.

Inferior Pedicle

The inferior pedicle was embraced by many surgeons when it was discovered that the superior portion (which was difficult to inset) of the vertical bipedicle was not necessary for circulation to the nipple-areola complex and that the inferior pedicle alone satisfied many of the goals of breast reduction: adequate circulation, good sensation, and breast-feeding potential.

Superior Pedicle

Although many surgeons embraced the inferior pedicle, the superior pedicle was still being used, especially in Europe and South America. Some surgeons strongly believed that the superior pedicle caused less ptosis, because it involved removing the heavy inferior tissue. The superior pedicle alone also had good circulation but was not as easy to inset. This pedicle often had to be thinned to allow for inset, causing concerns about the blood supply, sensation, and breast-feeding potential. When the anatomy is clearly understood, however, the only drawback is in breast-feeding potential, as it would be with any dermal (rather than dermoglandular) pedicle.

Central Pedicle

Some surgeons modified the inferior pedicle and instead removed the dermal component and based the nipple-areola complex on a central or posterior pedicle. This pedicle is based on the same blood supply as the inferior pedicle—the perforating artery through the pectoralis muscle that enters the breast usually just medial to the breast meridian a few centimeters above the inframammary fold. The perforating ar-

tery has accompanying venous drainage, which meant that surgeons did not need to rely as much on the dermal bridge for venous drainage as was needed with other pedicle designs.

Lateral Pedicle

Just as it became evident that the dual circulation through the vertical bipedicle was unnecessary, it also became evident that the dual circulation through the horizontal bipedicle was unnecessary. These bipedicles were not easy to inset without depressing the nipple-areola complex. The lateral pedicle was used, but it was overshadowed by the successful application of the inferior pedicle.

Medial Pedicle

The medially based pedicle was also discovered to have a good blood supply, but again, it was relatively ignored. Because surgeons mistakenly thought that the only innervation to the nipple came superficially through the lateral fourth intercostal nerve, they believed the medially based pedicle would interfere with sensation.

Liposuction-Only

Liposuction alone for breast reduction does not require a pedicle for the blood supply to the nipple. The nature of liposuction is that it leaves major vessels and nerves intact and thus revolutionized our approach to body contouring surgery in the 1980s and beyond. Liposuction does not work well when the breast tissue is mainly glandular. Because no skin is removed, the shape is limited by the ability of the skin to retract.

Free Nipple Grafts

Removing the nipple-areola complex completely and replacing it as a graft has not gained the popularity it probably deserves. It is a good method, especially in large breasts where neither sensation nor breast-feeding potential is an issue. Although free nipple grafts will lose some projection of the nipple and can result in some patchy depigmentation, the cosmetic result is usually good. The use of free nipple grafts allows unparalleled parenchymal resection. They are a good option in the very large breast or in a breast where the pedicle to the nipple-areola complex is particularly long.

**5**

71-1 Free nipple
graft technique

Patient Profiles

The following patient examples demonstrate a range of problems, with indications for different breast reduction techniques.

This 49-year-old patient was quite pleased with the results of her liposuction-only breast reduction. She was 4 feet 11 inches tall, weighed 52 kg (115 pounds), and wore a 34 D brassiere. Preoperative preparation included marking her for a vertical reduction in case the liposuction did not succeed. From the right breast 600 cc of fat was aspirated and from the left breast 575 cc was aspirated. Postoperatively, her nipple position was elevated by 1.5 cm on each side.

Although it would be ideal to perform liposuction-only breast reduction in young patients of normal weight, the breast tissue in these young women is often too thick and fibrous for liposuction. For example, liposuction alone in this 24-year-old patient would not be applicable. She was 5 feet 2 inches tall, weighed 54 kg (118 pounds), and wore a 34 DD brassiere. A vertical approach was used with 475 g removed on the left and 350 g on the right. The postoperative photos were taken at 6 months, when the scars were still hypertrophic.

This 37-year-old patient, who requested a liposuction-only breast reduction, was a better candidate than the previous patient shown, because she was older and slightly overweight. She was 5 feet 8 inches tall, weighed 77 kg (170 pounds), and wore a 38 DD brassiere. Because she had a relatively high nipple position, she underwent liposuction alone. Volumes removed were 625 cc from the right side and 675 cc from the left side. The patient lost upper pole fullness and was not happy with the shape. She returned at 1 year requesting a mastopexy.

This 22-year-old patient had breast reduction with an inverted-T skin resection pattern with an inferior pedicle for the nipple-areola complex. Unfortunately, because she was prone to hypertrophic scar formation, this was not the best approach for her. All the scars were noticeable, but the scar along the inframammary fold was particularly thick. Perhaps a vertical skin resection pattern would have been more appropriate for her.

This 37-year-old patient might have had too long a pedicle (18 cm [7 inches]) for the vertical approach with a medial pedicle. An inverted-T inferior pedicle would have been a good choice, but I decided to use free nipple grafts with a vertical skin resection pattern. A T was added because the length of the vertical scar exceeded 18 cm. She had 1355 g removed from the right breast and 1325 g from the left breast. She was 5 feet 5 inches tall, weighed 104 kg (230 pounds), and wore a 42 F/G brassiere. A further reduction, especially of the lower pole, would improve the result.

This 15-year-old patient is also a poor scar-former. She had surgery with the vertical pattern and a medially based pedicle for the nipple-areola complex. She was pleased with the result of the breast reduction and, fortunately, did not need an inframammary scar.

These images show how little fat was present in her breasts. Liposuction alone would not have been successful.

Most patients are appropriate candidates for the vertical approach. This 34-year-old patient had 625 g removed from the right breast and 720 g removed from the left breast. She was 5 feet 7 inches tall, weighed 84 kg (185 pounds), and wore a 36 F brassiere.

A vertical approach was successful for this 24-year-old patient. She was 5 feet 4 inches tall, weighed 56 kg (123 pounds), and wore a 34 D brassiere. She had 295 g removed from the right breast and 315 g from the left breast.

Most surgeons have the impression that the vertical approach does not work well for large breast reductions, but this patient shows the vertical technique's versatility. This 56-year-old woman was 5 feet 2 inches tall, weighed 82 kg (180 pounds), and wore a 38 H brassiere. From the right breast 1475 g was removed and 1400 g from the left breast. Photos taken 3 years postoperatively show maintenance of projection and shape.

Physical Examination and Preoperative Planning

Much of preoperative planning depends on a thorough understanding of breast aesthetics and the patient's goals. Photographs and digital imaging can be helpful to the patient when determining the desired size and shape.

The breasts are examined for masses or unusual shapes, asymmetries, or problems. Scoliosis, pectus deformities, and rib prominence need to be assessed. The chest circumference is measured at a level under the axilla. This measurement is the closest to bra size. If the chest measures 38 inches, then the patient is told to try a 38 size bra first. (Patients have often been wearing too tight a bra. Otherwise the breasts fall under the band or the back rides up too much.) The size along the inframammary fold is also measured. The inframammary fold is marked while the measuring tape is held along the fold. Next the distance between the suprasternal notch and the inframammary fold in the midline is measured. These measurements are for postoperative analysis. We also document that we discussed nipple sensation levels.

Inverted-T Technique

It is important to mark the breast preoperatively and determine the new nipple position. The key landmarks are the breast meridian, the inframammary fold, and the upper breast border. The surgeon should make the following determinations:

- Position of the inframammary fold (using the tape measure)
- Transposition of the inframammary fold to the front of the breast to determine the new vertical nipple position while being aware that the upper breast border will not change postoperatively
- Breast (chest wall) meridian to determine the new horizontal nipple position
- Breast meridian markings using the Wise pattern
- Distance of the vertical limbs
- Design of the areolar opening (either preoperatively or using a triangle if done intraoperatively)
- Pedicle design (usually superior, inferior, or central)
- Areas to be suctioned

The following measurements are also taken:

- Distance from the suprasternal notch to the nipple on both sides
- Distance from the inframammary fold to the nipple on both sides
- Suprasternal notch to the new nipple position on both sides (should be lower on a larger breast)

The following photographs demonstrate how the markings are made. These are the same initial markings as made for the inverted-T inferior pedicle.

Position of the Inframammary Fold: Using the Tape Measure

A good way to determine the new nipple position is to use the method described by Grading. He places a measuring tape along the fold under one breast and over the top of the other breast. He also uses a weighted tape measure around the neck to determine the true breast meridian. It is helpful to put the tape under both breasts and mark the position at the inframammary fold at the midline.

Determining the New Vertical Nipple Position

The fold level can vary from one patient to another. It can be marked with the tape measure, as shown above, or with the transposition of the marking anteriorly from the finger placed under the breast in the inframammary fold (left). Descriptions exist in which an arbitrary distance is marked from the suprasternal notch, or a point is marked in reference to the midpoint of the humerus. Unfortunately, these can be misleading, and reliance on anything but the level of the inframammary fold preoperatively can be disastrous. Sometimes the fold is abnormally high or low; in this case, the upper breast border is a better landmark because it does not change postoperatively. This patient's fold was almost at her elbow crease.

Determining the New Horizontal Nipple Position

The vertical breast meridian is marked by dropping a line from the midclavicle to the midbreast or midchest position. The line does not necessarily go through the nipple, but should be drawn for an ideal nipple position on the chest wall. If excessive lateral tissue will be removed, the true meridian would fall on the chest midline rather than the midline of the existing breast.

Breast Meridian Markings Using the Wise Pattern

This is the Wise pattern and is taken from his article and transferred onto x-ray film. The areola circumference measured 14 cm. The dotted lines show how the vertical limbs can be positioned differently, depending on how much skin is to be removed. The distance of the vertical limbs measured 5 cm.

Distance of the Vertical Limbs

In this patient, a superior pedicle was designed, and the distance of the vertical limbs was 6 cm. The vertical limbs of the resection are limited to 5 to 6 cm to prevent bottoming out of the breast postoperatively. The angle of separation between the vertical limbs depends on the amount of tissue to be resected, while trying to match the distance of the resulting skin length between the upper flaps and the lower incision along the inframammary fold.

Design of the Areolar Opening

The design of the areolar opening is determined either preoperatively or by using a triangle if done intraoperatively. The design in this patient was drawn as an inferior pedicle (a superior pedicle would be a better choice because of the short distance). Here the areolar opening has been drawn according to the Wise pattern and as a triangle in which the design will be determined intraoperatively after the resection.

The skin resection follows the Wise pattern with a keyhole opening for the nipple-areola complex and an excision that gives an anchor-shaped skin closure. Some surgeons design the keyhole preoperatively, whereas others prefer to incorporate an areolar opening once the resection has been performed. The areola itself is reduced and the new areola diameter is designed usually between 3.5 cm and 4.5 cm. This means that the skin opening should measure about 14 cm in circumference to avoid scar widening.

Pedicle Design

The pedicle design (usually superior, inferior, or central) is separate from the skin resection pattern. The patient above would be best served with a superior pedicle (as shown on the left) because the inset would be relatively easy. An inferior pedicle is also marked for comparison. The areas to be suctioned are the preaxillary fullness and the lateral chest wall fat.

Vertical Technique

The surgeon should make the following determinations and then mark the breasts accordingly:

- Position of the inframammary fold (using a tape measure) while being cognizant of the level of the upper breast border
- Breast (chest wall) meridian to determine a new horizontal nipple position
- Transposition of the inframammary fold to the front of the breast to determine the new vertical nipple position
- Breast meridian by rotating the breast laterally and medially (as shown by Lejour)
- Inferior extent of skin resection: 2, 4, and 6 cm above the inframammary fold
- Design of the areolar opening
- Design of the pedicle (usually superior or medial, sometimes inferior)
- Areas to be liposuctioned

These additional measurements are also made:

- The distance from the suprasternal notch to the nipple on both sides
- The distance from the inframammary fold to the nipple on both sides
- The suprasternal notch to the new nipple position on both sides (should be lower on the larger breast)
- The distance from the suprasternal notch to the inframammary fold in the midline
- The circumference of the new areolar opening (16 to 20 cm)
- The circumference around the skin resection pattern (divided in half, it should be the vertical scar length while standing)

The photographs that follow show how the markings are developed (these are the same initial markings as made for the inverted-T inferior pedicle).

Position of the Inframammary Fold: Using the Tape Measure

This photograph shows placement of the tape measure beneath the breasts and marking of the inframammary fold position. The level of the inframammary fold can vary considerably from patient to patient.

Determining the New Horizontal Nipple Position

Note that the meridian marking is independent of the current nipple position. The marking should be at the chest wall and breast meridian. If there is a significant amount of lateral breast tissue, select the chest wall meridian rather than the breast meridian. It is easy to be misled into marking the meridian through the nipple, but the surgeon should be careful to ignore the actual nipple position and mark where the nipple should be.

Determining the New Vertical Nipple Position

Transposition of the inframammary fold to the front of the breast will assist the surgeon in determining the new vertical position for the nipple. Placing the finger in the inframammary fold can be used alone, but marking the inframammary fold first with the tape measure helps considerably. With the finger maneuver, the tendency is to place the nipple position much higher than the true inframammary fold level. When the patient has a good deal of upper pole fullness, the surgeon can make the mark higher—the nipple should be at the most projecting part of the breast. But if the patient has little upper pole fullness, care must be taken to keep the new nipple position low. It is important to be aware that the upper breast border is an important landmark.

The new nipple position must be placed about 2 cm lower than what the surgeon is used to when performing an inverted-T procedure. This lowering is important to accommodate the increased projection that results with this procedure. It is also necessary because closure of a vertical ellipse tends to push the nipple even higher. (It is for this latter reason that the new nipple position needs to be lowered in the larger breast to achieve a symmetrical result.) If the patient does not have much upper pole fullness, this lowered nipple position is essential.

Marking the Breast Meridian by Rotating the Breast Laterally and Medially

Lejour marked the breast meridian resection pattern by rotating the breast upward and outward and then upward and inward to join the meridian marked on the upper breast to the meridian marked on the chest wall below the inframammary fold.

The design does not remove much skin. The closure should not be under tension. In fact, the skin can be quite loose at closure because the skin is not being used to hold the shape. We are so accustomed to using the skin brassiere to hold the shape with the inverted-T that many surgeons put lateral tension on the vertical closure. Not only is this unnecessary, but it can lead to wound-healing problems.

Inferior Extent of the Skin Resection

The vertical lines are then joined well above the inframammary fold. In a small reduction (less than 300 g) the lower portion of the U should be at least 2 cm above the inframammary fold. In a larger reduction (300 to 600 g), at least 4 cm of a skin bridge should remain. For a larger resection 6 cm and more should be left. This extra skin is important; otherwise the scar will go below the fold as the ellipse is closed. Some surgeons believe that a V closure is less likely to cause the scar to extend below the fold onto the chest wall, but the U is essential to encourage adequate removal of the excess subcutaneous tissue that causes a postoperative pucker.

Design of the Areolar Opening

Some surgeons prefer to design the areolar opening at the end of the resection. In this case the new nipple position was initially marked at the level of the inframammary fold, which was 27 cm from the suprasternal notch. Because the inframammary fold was low, it was decided to elevate the fold during the surgery (*above right*) and the new nipple position was elevated to 25 cm from the suprasternal notch. The vertical incisions were then joined as a triangle for a later areolar opening design.

For surgeons who prefer to mark the areolar opening before surgery, an opening is designed that will close as a circle. Lejour drew a mosque-shaped design, but I prefer a design that does not extend horizontally. The important aspect of the areolar opening is that it is a circle when closed. I usually make the areola about 5 cm in diameter. The ideal circumference of the areolar opening would be 16 cm but can be extended to 18 to 20 cm without significant areolar or scar widening.

The symmetry of the areolar design and skin resection pattern is checked.

Design of the Pedicle

The medial and laterally based pedicles have already been discussed in previous chapters (see Chapters 68 and 69).

With the superior pedicle, the areolar opening becomes the base. For most moderate-sized breasts this is a purely glandular pedicle. For larger breasts or for the nipple-areola that is significantly displaced inferiorly, a dermal component extending beyond the areolar opening is necessary. Insetting of these long glandular dermal pedicles can be challenging as the pedicle has to be folded in order for the nipple to be inset in the appropriate position. This is perhaps the major shortcoming of the superior pedicle and has led many to choose the medial pedicle over the superior for these patients.

Liposuction-Only

Preoperative planning for liposuction depends only on whether the patient wishes to undergo a definitive procedure if the liposuction alone does not produce much aspirate. The breast is marked preoperatively to indicate the areas of increased fullness and to determine which areas will need the most concentration.

The patient is usually marked for a vertical approach and then the areas to be suctioned are also marked. If the patient does not have much upper pole fullness, this area is avoided. On the other hand, if this area is not suctioned, there will be little upward movement of the nipple-areola complex. Some superficial liposuction above the areola is needed for upward migration.

This patient had a high nipple position and lots of upper pole fullness. She wanted to try liposuction-only breast reduction, but she was 18 years old and not overweight at 55 kg (122 pounds). She was 5 feet 2 inches tall and wore a 38 C brassiere. She agreed to have the vertical approach if liposuction failed. Unfortunately, only a minimal amount of fat was removed with liposuction-only.

She then underwent a vertical breast reduction with a medial pedicle; 620 g was removed from the right breast and 570 g from the left breast. The photograph on the left shows how little of the breast tissue was fat.

Operative Technique

Inverted-T Breast Reduction

Inferior Pedicle

Care must be taken not to undermine the full-thickness pedicle when incising it down to the chest wall. The pedicle is “floppy,” so care must be taken not to disturb the perforating artery branch from the internal mammary system through the pectoralis muscle. This perforating artery is not visualized during the dissection. Although vessels from the dermal bridge inferiorly are not as robust, they still can contribute significant arterial inflow and venous drainage to the inferior pedicle. This can be important when the perforating artery is negligible, especially because there is no way to determine this preoperatively. The inferior pedicle is therefore probably more reliable than a purely central pedicle.

The parenchymal resection follows the skin resection pattern. With the inferior pedicle, the flaps are drawn together over the pedicle after resecting breast tissue superiorly, inferiorly laterally, and inferiorly medially. An inferior pedicle has a relatively broad base of at least 6 to 10 cm and is a full-thickness pedicle. Care must be taken because it is not difficult to inadvertently undermine the pedicle.

A skin-length discrepancy often occurs horizontally. An attempt is made to bring the tissue toward the meridian to try to avoid a boxy shape, while trying to flatten the resultant dog-ears as they are chased medially and laterally. The result is a breast shape held together by the skin brassiere. The use of drains and antibiotics varies from surgeon to surgeon.

Central Pedicle

The illustrations below and on p. 2562 are derived from John Bostwick's description of the central pedicle. His concept of the arterial blood supply is clearly outlined, showing how arterial input is preserved with the central pedicle incisions.

Medial and lateral resections narrow the breast. Central pedicle vascularity is preserved by the central and peripheral vessels. Superior and inferior resections permit lifting the breast and removing ptotic tissue while shifting the breast parenchyma upward. The central pedicle is nourished by musculofascial perforating arteries and by flow coming from the periphery via the medial and lateral intercostal perforating and external mammary arteries. The central mound must not be resected to such a degree that the underlying perforating vessels coursing into it and into the areola are compromised.

The central pedicle surmounted by the nipple-areola complex is moved to its new position, and the incisions are closed in a lateral to medial direction. The excellent mobility of the pedicle and the nipple-areola make this technique especially good for large ptotic breasts.

Free Nipple Grafts

Free nipple grafts may be used independently of the skin resection pattern chosen. Some form of pedicle must be retained as a bed for the graft; this usually involves leaving some tissue attached to the areolar opening. Since no significant length is involved, maintaining blood supply to this tissue is not an issue. It is usually superiorly based with a triangle of tissue removed inferiorly to create a circle.

This resection will permit some narrowing of the breasts during closure. The inferior and lateral resected portions of the breast parenchyma are shown.

Vertical Breast Reduction

This technique is described in Chapters 68 and 69.

Liposuction-Only Breast Reduction

Since no pedicle is needed for the nipple-areola complex and there is no skin undermining, liposuction poses fewer risks to blood supply. Nor does it typically impair sensation and breast-feeding potential.

Some claim that liposuction-only is good for patients with medical problems because it is less invasive. Liposuction should be treated as a major surgical procedure, however, and the recovery is not necessarily easier.

The breast is infiltrated with tumescent-type fluid. Liposuction is performed through one or two small incisions. If the surgeon wants to achieve some skin retraction and nipple elevation, then some form of superficial liposuction must be performed above the areola. Care must be taken not to suction too much so as to avoid reducing upper pole fullness to any significant degree. Unfortunately, it is difficult to achieve much reduction in the upper outer quadrant because this tissue tends to be fibrous rather than fat.

Perimenopausal women have more fat tissue in the breasts than do teenagers. If a young woman is thin, it is unlikely that much tissue can be removed with liposuction. It is important to mark her for an open reduction if the liposuction does not remove much fat. As with other liposuction procedures, it can take about 6 weeks for the swelling to decrease and about 6 months for the breast to soften and for the lumpiness to settle.

This patient successfully underwent liposuction-only breast reduction. She had pre-operative markings for a vertical breast reduction in case liposuction alone was unsuccessful. Once the fluid settled, approximately 600 cc of fat was removed from each breast.

Postoperative Management

Inverted-T Skin Resection

Complications with inverted-T techniques usually consist of minor wound-healing problems, especially at the T junction. Nipple-areola necrosis can occur, and patients must realize that all breast reductions involve some reduction of blood supply to the nipple-areola complex. Patients rarely complain about the scars and shape because they are so pleased with the reduction in volume. On the other hand, it is difficult to prevent and treat the boxy shape and dog-ears that are early problems or the pseudoptosis and bottoming out that occur with time.

Free Nipple Grafts

With any skin resection pattern, free nipple grafts are covered with a bolus tie-over type of dressing that is left in place for approximately 1 week. Once the dressing is removed, the areola will look dusky, and portions of the nipple may look dark and desiccated. This is allowed to declare itself; over time the outer surface of the skin separates. Some depigmentation may occur, especially in dark-skinned individuals. Depigmentation may take more than 6 months to settle and repigment.

This 37-year-old patient had a vertical reduction designed, but the pedicle would have been excessively long (18 cm [7 inches]). It was therefore decided to convert to free nipple grafts.

In this patient a vertical skin resection (with a T to remove redundant skin) and free nipple grafts were used. The photograph shows the bolus dressings at the end of the procedure. Although 1355 g was removed from the right breast and 1325 g from the left breast, that was probably not enough and more should have been removed.

Six days after surgery, the nipple-areola complex looked a bit frightening. This is actually typical for free nipple grafts in the initial postoperative period.

Patients need to be informed preoperatively so that they can accept this stage. These photographs can help to reassure patients in the postoperative period.

This photograph of the same patient 3 weeks later shows a bit of blistering, but good color and nipple projection.

Four months after surgery the breasts appear underresected, but the free nipple grafts healed well.

This 27-year-old woman had problems with depigmentation. She had 2025 g removed from the right breast and 1770 g from the left breast. The result was less than satisfactory. The photographs were taken 7 days, 3 months, and finally 14 months postoperatively. She is scheduled for a revision.

Vertical Skin Resection

Vertical skin resection has a higher revision rate, possibly because the problems (most often puckers) can be more easily treated with the vertical approach than the problems (dog-ears and bottoming out) with the inverted-T techniques.

The vertical approach has a definite learning curve; it is best for surgeons to start with the opposite breast in a reconstruction patient or with relatively small reductions. Patients requiring larger reductions may be more accepting of irregularities. Patients who are well informed preoperatively understand that it may take weeks or even months for the shape to settle. The inverted-T technique has a learning curve as well, but practicing these techniques in residency reduces anxiety.

Puckers often can be revised under local anesthesia in the office. It is important to advise patients that a revision will not be considered until a full year has elapsed. Large puckers, correction of asymmetry, or further volume reduction may require general anesthesia.

Nipple necrosis is a serious complication. When it occurs, little can be done. Breast reduction is a blood supply-reducing operation. Although new nipples can be made (as in breast reconstruction), they do not look as good as the original.

Wound-healing problems still occur, especially at the lower end of the vertical incision, with larger breast reductions, and in the more obese patients. Again, patients are asked to leave these areas open to heal and to return for removal of any exposed deep sutures.

As nipple and areola sensation returns, patients may experience hypersensitivity, along with tingling and discomfort. Sensation may not return completely.

Preoperative

10 days postoperatively

18 months postoperatively

This 24-year-old patient is shown preoperatively, as well as at 10 days and 18 months postoperatively. She had a vertical approach with a medial pedicle; 295 g were removed from the right breast and 315 g from the left breast. Puckers that are evident initially usually settle and disappear. Patients are informed before surgery that they must wait at least 1 year before any kind of revision is considered. Preoperative counseling advises that 95% of patients worry about puckers, swelling, and asymmetry and that only 5% actually need a revision.

Liposuction-Only

Liposuction-only breast reduction does not require much in the way of postoperative care. Compression dressings are indicated, but it takes weeks for the swelling to settle and months for the induration to soften. Too much compression has been shown to cause skin necrosis.

Outcomes and Complications

Multiple studies have shown that breast reduction is outstanding in terms of outcomes research (something insurance providers seem to ignore). Back pain, neck pain, shoulder grooving, rashes under the breasts, and even headaches are significantly relieved. Patients feel much more comfortable, and they can more easily participate in sports and other physical activities. They sit, stand, and walk with better posture and have better exercise tolerance.

Many patients comment on how much better they feel immediately after surgery—the evening of the same day. Patients have the surgery as day procedures, or they may stay over one night in the hospital. The vertical approach has reduced operating time in half. It now takes us about 90 minutes to complete a breast reduction, whereas it used to take about 3 hours for an inverted-T inferior pedicle approach. Both pain levels and recovery time are also significantly reduced.

Immediate Complications

Immediate complications may include hematoma, seroma, circulation problems, and infection.

Hematoma

Hematoma had not been a problem until I (E.H.-F.) started using tumescent-type infiltration. It is clear that some of the vessels (the perforating artery from the pectoralis muscle) were in spasm from the infiltration in at least two of my cases. One must actively find these vessels and cauterize them.

This 52-year-old patient was 5 feet 6 inches tall, weighed 76 kg (168 pounds), and wore a 42 DD brassiere. She had 740 g removed from her right breast and 700 g from her left breast. She was taken back to the operating room that evening to evacuate the hematoma. The postoperative photograph shows her result at 6 weeks.

Seroma

Seromas can occur after breast reduction surgery but do not necessarily need to be aspirated. Some surgeons place drains and others do not. I (E.H.-F.) no longer use drains unless the operation has been particularly “wet” or the reduction has been large.

Nipple-Areola Necrosis

The nature of breast-reduction surgery is such that in removing a significant amount of breast tissue we reduce the blood supply. Often the nipples look pale or dusky at the end of the operation. Recovery is expected, but the course is unpredictable. The literature contains numerous suggestions as to how the nipple-areola complex may be salvaged. The problem is that there is no good way of evaluating which areolae will completely recover, blister, develop a necrotic edge (that heals uneventfully), or progress to frank necrosis. Examination does not reveal the answers. Clear engorgement and congestion could herald venous trouble that might respond with reoperation. But for those of us with significant experience, venous problems are rarely the cause. The areola usually is somewhat pale and dusky. Capillary refill testing may not be clear. Tissue oxygenation assessment is not accurate.

Active intervention is fraught with difficulty and potential complications. Removing sutures may delay healing. We have all seen those patients who healed well and in whom intervention could have caused more complications. Is it worth removing the nipple and areola and converting it to a free graft when the result could be less than satisfactory (with decreased projection, patchy hypopigmentation, loss of sensation, and loss of breast-feeding potential)? If we could judge the difference between the “normal” pedicle and compression or kinking, reoperation might be of value. All we

know now is that clear venous congestion would probably benefit from surgery. But this is rare. For the same reason, applying leeches would only treat venous congestion; most of us believe that nipple necrosis develops from lack of arterial inflow. This inflow restriction is caused by the surgery, and intervention has little to offer.

This patient developed necrosis that healed without intervention. The first postoperative photograph shows the patient 4 weeks after surgery. The second postoperative photograph is at 6 weeks, and the final photograph is at 4 months. Intervention would probably result in a less satisfactory outcome.

These photos show an example of complete necrosis. The right areola is slightly dusky at the 1 and 2 o'clock positions, but this is quite common in the immediate postoperative period. It is difficult to decide whether to observe or intervene.

The first photograph was taken at 10 days postoperatively, and the final photograph was taken at 3 months postoperatively. The necrotic tissue was removed in the office. The patient declined any form of reconstruction.

Flap Necrosis

Flap necrosis occurs more often with the inverted-T techniques, especially at the T junction itself.

Postoperatively this patient had an unusual pattern of necrosis accompanied by an infection in the right breast. Necrosis at the T on the left breast is fairly typical of the inverted-T techniques (although it is not usually associated with this degree of redness).

She healed well after debridement and healing by secondary intention. The final photographs are shown at 15 years postoperatively.

Infection

Infection can occur with any operation. It remains controversial as to whether to treat breast surgery patients prophylactically with antibiotics and, if so, for how long.

Late Complications

Late complications are related more to shape. Problems with the inverted-T techniques are related to the inframammary scar and the problem of medial and lateral dog-ears. The shape can be somewhat boxy and projection compromised.

Scars

This patient was a bad scar-former, but she convinced me to accept Lejour's challenge to try to improve scarring in my procedures.

With the vertical approach, the scar may fall below the inframammary fold if the markings are carried down to the fold initially. The lower end of the vertical skin excision should end about 2, 4, or 6 cm above the inframammary fold. This is important not only because the inframammary fold tends to rise with the vertical approach, but also because of the ellipse effect: the scar becomes longer in a vertical direction when the ellipse is closed.

Even 2 cm above the fold was not enough in this patient. Her inframammary fold was raised more than I expected.

Shape

Until the vertical approach became a routine technique in our practices, we were not aware that the results with the inverted-T were somewhat unsatisfactory. We had become accustomed to the boxy shape resulting after the inverted-T and had accepted it as inevitable. Fortunately, the coning of the breast tissue that occurs with the vertical approach has eliminated this problem. The problem of chasing lateral and medial dog-ears has also disappeared because the vector of pull is horizontal.

Although many patients have satisfactory scars with the inverted-T approach, it is not uncommon for patients to request correction of the medial and lateral puckers. However, there is really no good solution for these dog-ears.

Initially, when using the vertical approach, I (E.H.-F.) had a higher revision rate, about 5%, for persistent puckers at the inferior end of the vertical scar. Once I realized that the pucker resulted from excess subcutaneous tissue rather than excess skin, the revision rate decreased.

With the vertical approach the shape is better, with narrowing of the breast base and more projection, and lasts longer. The result at 1 year is the same as the result at 2, 3, and 10 years. With the inverted-T approach, the shape deteriorates to some degree each year, particularly when a patient became pregnant after surgery.

This patient initially had a good result with the inverted-T technique using an inferior pedicle. After having two children, her breast skin stretched and the shape bottomed out (*right*).

Much depends on skin elasticity and genetics. This patient had one pregnancy and the shape held.

It is unfair to attribute results to one skin resection pattern versus another, and it is probably even more unreasonable to compare techniques with different pedicles. The first patient had an inferior pedicle and the second patient had a medial pedicle. Was it the patient, the skin resection pattern, or the pedicle weight that made the difference? Probably a combination of the three influences the result, but the pedicle weight is a significant factor. With the medial or superior pedicle, the heavy inferior breast tissue is removed, leaving the desired superior breast tissue. With the inferior pedicle, we are leaving what we want to remove and removing what we want to leave. The skin resection pattern is partly to blame. Skin and dermis are notoriously unre-

liable at holding anything when stress is applied. In fact, both skin and dermis will adapt and deform with stress. The vertical approaches use the breast to shape the breast, and the inverted-T approaches use the skin to shape the breast. Shaping works best when it relies on inelastic tissues to take the stress.

Underresection

Recurrent ptosis is the result of leaving too much inferior breast tissue. Underresection is a particular problem in vertical breast reductions because it is difficult to gauge how much breast tissue should be removed. Surgeons who are comfortable preoperatively evaluating the amount of breast tissue to be excised should make certain they actually remove that amount and are not fooled into thinking that the breasts are smaller than they are at the end of surgery.

This patient did not have enough tissue removed in the lower pole (and her nipples were placed too high). She was marked for further excision, both by direct excision and liposuction.

This patient needed removal of lateral breast tissue and chest wall fat. The problem here was not one of underresection; rather, it was the result of not recognizing that the inframammary fold rises—especially laterally—and that the fat between the old and new inframammary fold should be removed.

Asymmetry

Asymmetry usually occurs in patients whose breasts are asymmetrical to start with. This series of images shows how the asymmetry was corrected. The solution did not rely on skin resection but on adjustment of the parenchyma with removal (both directly and with liposuction) of the areas of excess.

Puckers

Puckers are more common in the vertical techniques, whereas medial and lateral dog-ears are more common in the inverted-T skin resection patterns.

It is tempting to try to remove the puckers with a T incision, but a vertical (small) skin excision is better. The key is to recognize that the problem is caused by excess subcutaneous tissue rather than excess skin.

In this patient, puckers were removed through a short transverse or T excision. The initial result was acceptable. This example shows that a surgeon's revision rate will depend on his or her threshold for revision.

This patient's pucker (mostly subcutaneous tissue) was excised through a vertical incision. It is important to mark the inframammary fold first to make sure that the scar does not go below the fold. With a horizontal excision it can be difficult to know exactly where to put the transverse scar. The problem also then becomes one of chasing dog-ears horizontally.

This patient had more extensive problems with puckers. Cross-hatching shows the area of excess subcutaneous tissue. The skin excess is marked vertically. Puckers are less a problem of excess skin than an excess subcutaneous tissue.

It appears that this patient would require a T closure to correct puckers. In fact, a small vertical excision, not extending past the marked inframammary fold, with horizontal excision of underlying subcutaneous tissue is the procedure of choice.

Results

Liposuction-Only

This 45-year-old patient was 5 feet 7 inches tall, weighed 73 kg (160 pounds), and wore a 38 DD brassiere. She had 1000 cc of fat aspirated from the right breast and 900 cc of fat aspirated from the left breast. She is shown here at 2 months postoperatively. The right nipple rose 2.5 cm and the left nipple rose 2 cm. Note the elevation of both the breast and the nipple in relation to the patient's elbow crease. The result will be acceptable to some patients and not acceptable to others; the loss of upper pole fullness makes the shape appear to be more ptotic, even though there is a measurable elevation.

Inverted-T Techniques

This 26-year-old patient underwent a breast reduction using the inverted-T technique and an inferior pedicle. She was 5 feet 1 inch tall, weighed 88 kg (193 pounds), and wore a 42 DD brassiere. She had 910 g removed from the right breast and 1050 g from the left breast. The patient is shown 2 months after the procedure. The result is somewhat boxy and the cleavage is narrowed, because the breast cannot be coned as easily as it can with the vertical approach. The inverted-T techniques tend to result in a wider breast base than the vertical techniques, because the skin and parenchyma are closed using a horizontal elliptical excision of skin and breast tissue, whereas the vertical approach uses a vertical elliptical excision of skin and breast tissue.

This 26-year-old patient had a breast reduction with an inverted-T skin resection pattern and an inferior pedicle for the nipple. She was 5 feet 8 inches tall, weighed 77 kg (170 pounds), and wore a 38 D brassiere. She had 640 g removed from the right breast and 525 g from the left breast. Note the wide breast base.

This 20-year-old patient had an inverted-T skin resection with an inferior pedicle for the nipple. She was 5 feet 5 inches tall, weighed 73 kg (160 pounds), and wore a 40 DD brassiere. She had 600 g removed from the right breast and 540 g from the left breast.

Preoperative

3 years postoperatively

20 years postoperatively

This 19-year-old patient underwent an inverted-T skin resection with an inferior pedicle for the nipple. She was 5 feet 1 inch tall, weighed 59 kg (130 pounds), and wore a 36 D brassiere. She had 255 g of tissue removed from the right breast and 285 g from the left breast.

She had gained weight in the photographs shown at 3 years after surgery. The final postoperative photographs show her, with some weight loss, 20 years later. These images show evidence of recurrent ptosis, or bottoming out that can occur with time. Note that both the weight gain and weight loss tend to occur mainly in the upper pole.

Inverted-T Techniques With Free Nipple Grafts

Case from John Bostwick III, MD

These images show a 62-year-old woman 2 years after breast reduction. Because her history of smoking and desire for a significant reduction could cause problems, a breast reduction with an inverted-T skin resection and free nipple grafts was done. She was pleased with her reduced breast size and even regained some nipple sensation.

Case from John Bostwick III, MD

In this patient, 1700 g were removed from each breast. She is shown at 1 month post-operatively. The nipple-areola grafts healed well, but superficial desquamation of the areolar skin is still evident. The pigmentation is expected to diminish with time.

Vertical Techniques

Preoperative

1 month postoperatively

1 year postoperatively

This 21-year-old patient was 5 feet 3 inches tall, weighed 91 kg (200 pounds), and wore a 38 DD brassiere. She had 525 g removed from the right breast and 480 g removed from the left breast. She is shown 1 month and 1 year after surgery. Note that the breast tissue is narrowed as the breast is coned.

Preoperative

10 days postoperatively

1 year postoperatively

This 49-year-old woman was 5 feet 1 inch tall, weighed 69 kg (153 pounds), and wore a 38 D brassiere. She had 260 g removed from each breast. She is shown 10 days and 1 year postoperatively.

Preoperative

2 weeks postoperatively

2 years postoperatively

This 56-year-old woman was 5 feet 7 inches tall, weighed 64 kg (140 pounds), and wore a 36 DD brassiere. She had some asymmetry, and the new nipple position should have been lowered on the larger side. She had 260 g removed from the right breast and 225 g from the left breast. The first postoperative views were taken 2 weeks after surgery; the final views were taken 2 years after surgery. Note that the nipple position is higher on the larger side. Closure of the vertical ellipse tends to push the nipple higher on the larger breast.

Preoperative

6 weeks postoperatively

3½ years postoperatively

This 64-year-old patient had 700 g removed from her right breast and 800 g from her left breast using the vertical approach and a medial pedicle. She was 5 feet 6 inches tall, weighed 82 kg (180 pounds), and wore a 40 DD brassiere. She is shown 6 weeks and 3½ years postoperatively.

Preoperative

2 weeks postoperatively

4 years postoperatively

This 51-year-old patient was 5 feet 2 inches tall, weighed 81 kg (178 pounds), and wore a 38 DD brassiere. She had a vertical breast reduction with a medial pedicle and had 570 g removed from the right breast and 690 g from the left breast. An additional 475 cc of fat was removed from the preaxillary area and lateral chest wall area. She is shown 2 weeks and 4 years after surgery.

Concluding Thoughts

The best breast reduction is the breast reduction that the surgeon does the best. There is no “right” way to approach breast reduction, but surgeons must have the ability to use several different approaches, depending on the circumstances (see the table below). It is important to understand that the pedicle, the skin resection pattern, and the parenchymal resection pattern can be used in various combinations. Many of us who perform vertical approaches like the fact that we remove the heavier inferior breast tissue, reshape the parenchyma, and then allow the skin to redrape. We believe that this not only results in fewer scars, but also provides a better shape with good projection. We have also found that this shape tends to last longer than procedures that rely on the skin as a brassiere or support.

Choosing the Best Option*						
Breast Characteristic	Skin Excision Pattern and Final Scar					
	Liposuction-Only	Periareolar	Vertical	Short Horizontal T, J, or L	Longer Horizontal L	Traditional Full-Length Horizontal T
Size of Reduction						
<500 g						
500-1000 g						
>1000 g						
Skin Elasticity						
Normal						
Inelastic						
Skin Excess						
Minimal						
Moderate						
Massive						
Parenchyma						
Firm and fibrous						
Soft and fatty						
Skin-Parenchyma Relationship						
Firmly adherent						
Loosely adherent						

*General recommendations for choosing skin excision patterns in breast reduction are based on the characteristics of the breast. Taking into account the size of the reduction, skin elasticity, skin excess, quality of the parenchyma, and the skin-parenchyma relationship, the appropriate skin excision patterns are indicated. A given skin excision pattern can usually accommodate a number of parenchymal resection techniques.

Clinical Caveats

The procedure must be adapted to the needs and desires of the patient, but within the experience and expertise of the surgeon. No one procedure fits all patients, but many surgeons now think that the vertical approach (with whichever pedicle is most comfortable for the surgeon) has wide applicability.

The shape of the breast is determined by the resection, specifically which parts of the breast are resected, and how the rest of the breast is reshaped. The skin plays little role in shaping or maintaining breast shape.

The longevity of the result depends not only on the technique but perhaps even more on the patient's tissues; specifically, the quality and elasticity of the skin.

Liposuction is best for those patients for whom breast shape and projection is not a priority. The appeal of this technique is that it is less likely to cause problems with scarring, circulation, sensation, or breast-feeding.

Liposuction alone has limited usefulness in those patients for whom it would be the most desirable: teenagers. In teens who are close to ideal body weight, it is unlikely that much of the breast is composed of fat. Perimenopausal women have the highest volume of breast fat, especially if they are overweight. These patients often have more ptosis, and shape can be an issue.

The inverted-T skin resection pattern may still be the best choice for patients with large breasts or in massive-weight-loss patients who have a considerable amount of excess skin.

Inverted-T techniques use the skin to shape the breast. It takes a different mindset to change from exact measurements and short vertical limbs in the inverted-T procedures to looser skin and long vertical limbs which are needed to accommodate projection in the vertical procedures.

It is critical in both inverted-T and vertical approaches to properly mark the new nipple position. A nipple that is too high is difficult or impossible to correct. Arbitrary measurements from the suprasternal notch should be avoided. The nipple should be designed at the level of the inframammary fold and in relation to the upper breast border. With the vertical approach, this position should be somewhat lower to accommodate the increased projection.

The inframammary fold can rise with some of the vertical techniques and tends to drop beneath the horizontal scar with the inverted-T technique.

Each method of breast reduction has advantages and disadvantages. The surgeon should evaluate each patient's desires in light of her physical presentation. No one technique satisfies all. Each surgeon should be comfortable with several techniques, even if he or she prefers one technique for most patients.

Annotated Bibliography

Asplund O, Davies DM. Vertical scar breast reduction with medial flap or glandular transposition of the nipple-areola. *Br J Plast Surg* 49:507-514, 1996.

Vertical scar breast reduction is a well accepted technique that the authors state improves the shape and projection of the breast and leaves no horizontal scars. Lassus and Lejour described superiorly based nipple flaps; Asplund and Davies describe a medially based flap or glandular transposition of the nipple in small reductions. After a short learning curve, the complications have been few and minor.

Courtiss EH. Reduction mammoplasty by suction alone. *Plast Reconstr Surg* 92:1276-1284, 1993.

This was the first in a series of articles documenting the use of liposuction alone for breast reduction.

Courtiss EH, Goldwyn RM. Reduction mammoplasty by the inferior pedicle technique. An alternative to free nipple and areola grafting for severe macromastia or extreme ptosis. *Plast Reconstr Surg* 59:500-507, 1977.

The Courtiss articles led to the acceptance in North America and beyond of the inferior pedicle inverted-T breast reduction as the procedure of choice for the majority of patients.

Daane SP, Rockwell B. Breast reduction techniques and outcomes: a meta-analysis. *Aesthet Surg J* 19:293-302, 1999.

This and the preceding three articles present outcomes research that document significant improvement in patients undergoing reduction mammoplasty surgery.

Goldwyn RM. *Reduction Mammoplasty*. Boston: Little Brown, 1990.

This classic textbook, edited by one of the most respected plastic surgeons, offers an excellent historical review of the various approaches to breast-reduction surgery. Practicing plastic surgeons can learn a great deal by reading and rereading what has been written here.

Gradinger GP. Reduction mammoplasty utilizing nipple-areola transplantation. *Plast Reconstr Surg Clin Plast Surg* 15:641-654, 1988.

Gradinger reviews free nipple grafts using an inverted-T skin resection pattern. This technique has fallen out of favor, but probably should be considered more often.

Lassus C. A 30-year experience with vertical mammoplasty. *Plast Reconstr Surg* 97:373-380, 1996.

The author discusses the evolution of his vertical mammoplasty breast reduction technique. In a 30-year period there were few complications, indicating that it is a safe procedure producing long-lasting results.

Lejour M. *Vertical Mammoplasty and Liposuction of the Breast*. St Louis: Quality Medical Publishing, 1993.

The many publications of Lassus and Lejour increased acceptance of the vertical skin resection pattern.

Nahai FR, Nahai F. MOC-PSSM CME article: breast reduction. *Plast Reconstr Surg* 121 (1 Suppl):S1-S13, 2008.

The goal of this continuing medical education module was to present the preoperative assessment, formation of a surgical treatment plan and its execution, postoperative patient management, and identification and treatment of early and late postoperative complications in breast reduction surgery.

Pitanguy I. Surgical correction of breast hypertrophy. *Br J Plast Surg* 20:78-85, 1967.

Pitanguy detailed the different pedicles used for breast reduction using the inverted-T skin resection pattern.

Robbins TH. A reduction mammoplasty with the areola-nipple based on an inferior pedicle. *Plast Reconstr Surg* 59:64-67, 1977.

This article first described the inferior pedicle with an inverted-T skin resection pattern and led to an almost uniform acceptance of the procedure as the standard of care in breast-reduction surgery.

Sampaio Góes JC. Periareolar mammoplasty double skin technique. *Breast Dis* 4:111-127, 1991.

Many articles in this list are important landmarks in the attempt to reduce scars and limit them to the periareolar location only.

Spear SL, Howard MA. Evolution of the vertical reduction mammoplasty. *Plast Reconstr Surg* 112:855-868, 2003.

The authors present a good review of the main variations of the vertical skin resection pattern. This article highlights the differences between the techniques of Lassus, Lejour, Hammond, and Hall-Findlay and then details Spear's preferred approach.

CHAPTER 72

Mastopexy and Breast Reduction in Massive-Weight-Loss Patients

J. PETER RUBIN, JONATHAN TOY

The rate of obesity continues to rise in the United States at an alarming rate, with more than 35% of the population considered obese. To lower their risk of obesity-related medical conditions, many people have sought to lose weight either through bariatric surgical procedures or lifestyle modification—diet and exercise. After massive weight loss, defined as the loss of more than 23 kg (50 pounds), the individual is often left with redundant skin and excess subcutaneous tissue. For this reason, an increasing number of patients are seeking plastic surgery consultation for correction of these deformities.

After the abdomen, the next body area with which many women are most concerned is their breasts and their appearance after massive weight loss. Many of these women had full breasts before their weight loss and have severe deformities after reaching their goal weight. Extensive and asymmetrical volume deflation, descent and medialization of the nipple-areola complex, distortion of shape, including breast flattening, coupled with an excess of inelastic skin relative to the breast parenchyma makes the breast deformities difficult to treat. During the evolution of breast reduction and mastopexy procedures after massive weight loss, plastic surgeons have focused on key aesthetic goals: repositioning of the nipple-areola complex, minimization of scar and proper scar placement, achieving adequate projection and medial fullness of the breast, and long-term stability of the results.

The technique of dermal suspension, parenchymal reshaping, and selective autologous tissue volume augmentation (autoaugmentation) in massive-weight-loss patients was developed with the principles of prior breast reshaping procedures in mind. Earlier techniques in breast reduction and mastopexy relied on dermal support to maintain shape and were dependent on skin resection patterns. Bottoming out of parenchyma with recurrent breast ptosis were negative features of the techniques relying on these principles. The introduction of the vertical mammoplasty by Lassus and expanded on by Lejour heralded more long-lasting and reliable methods of parenchymal reshaping, with less reliance on the dermal envelope for shape. Others developed methods of dermal suspension to elevate breast tissues as well as techniques to increase upper pole fullness with sutures to affix the parenchyma to surrounding structures. Graf and Biggs devised a dermoglandular pedicle that is passed under a partial-thickness loop of pectoralis muscle and fixed to the pectoralis fascia under the breast. Closure of medial and lateral pillars behind the flap helps to secure elevation.

The approach to the breasts of massive-weight-loss patients differs from techniques used for non-weight loss patients. Short-scar techniques in general have a limited role because of the need for more extensive skin resection. In our technique of dermal suspension, parenchymal reshaping, and selective autoaugmentation, the vascularity of the nipple-areola complex is ensured with a central dermoglandular pedicle. A modification of the traditional Wise pattern allows control of the skin envelope and nipple position.

Advantages and Disadvantages of Mastopexy and Breast Reduction in Massive-Weight-Loss Patients

Advantages

- A lateral axillary roll deformity can be eliminated.
- Autoaugmentation of the breast may be achieved with the use of tissue in the lateral axillary roll.
- The skin envelope can be easily controlled.
- Parenchymal reshaping is facilitated.
- Long-lasting elevation of the parenchyma is achieved.

Disadvantages

- Scars are long.
- Operative time is increased because of the large areas to be deepithelialized.
- A high degree of intraoperative tailoring is required.

In this chapter we highlight the anatomic changes observed in the breast after weight loss and present details of a versatile technique to achieve an aesthetically pleasing result.

Goals of Breast-Reshaping Surgery

- To use all available breast tissue while maintaining the ability to recruit additional autologous tissue
- To address nipple position
- To restore superior pole projection
- To reshape the skin envelope without relying on it for support
- To eliminate the lateral skin roll
- To create a discrete “lateral sweep” or defined lateral curvature to the breast shape

Indications and Contraindications

Indications for dermal suspension and parenchymal reshaping with selective autoaugmentation include severe ptosis with deflated breast shape and adequate parenchymal volume to build a breast mound. Although not required to perform this procedure, a lateral skin roll allows recruitment of chest wall tissue into the breast mound.

There are relatively few contraindications to the procedures mentioned. Patients who are current users of tobacco products are instructed to stop for 1 month before and after surgery. We routinely screen patients with a positive history of tobacco use with a cotinine urine test before surgery. Patients who have had previous breast surgery must be carefully evaluated to ensure that their old scars will not compromise any planned procedure. Patients with active intertrigo or diffuse fibrocystic disease may also not be ideal candidates. Also, inadequate parenchymal volume to build a breast mound is a relative contraindication, although lateral roll volume needs to be considered and may add sufficient volume. Finally, patients with a BMI higher than 35 may not be ideal candidates.

Patient Profiles

Good candidates for dermal suspension and parenchymal reshaping with selective autoaugmentation include those with parenchymal deficiency relative to skin with breast deflation and lateral skin roll. Poor candidates include those with no lateral skin roll, a short nipple-to-inframammary fold distance, and minimal breast ptosis.

This 40-year-old massive-weight-loss patient had lost 61 kg (135 pounds) before breast surgery and presented with a BMI of 33.8. She was a good candidate for the dermal suspension/parenchymal reshaping technique. These images demonstrate extensive breast ptosis and parenchymal deflation with a significant increase in the distance from the nipple to the inframammary fold; she had a sizable lateral skin roll. (Results are discussed on p. 2614.)

This 44-year-old massive-weight-loss patient was not an ideal candidate for the dermal suspension/parenchymal reshaping technique. Although she had lost more than 45 kg (100 pounds) after gastric bypass surgery (a BMI change from 41.8 to 25.4), her breasts were not extensively deflated and she had moderate ptosis. There was only modest parenchymal volume and minimal lateral skin roll for autoaugmentation. Postoperative images 3 months after a combined mastopexy-augmentation with saline implants and Wise pattern skin resection demonstrate excellent nipple repositioning and improvement in breast shape and projection. The use of the Wise pattern skin resection was necessary to adequately control the breast envelope and deal with the skin excess.

Pertinent Anatomy

Women who have undergone massive weight loss have characteristic breast deformities that distinguish them from other women seeking correction of volume loss and breast ptosis. The Pittsburgh Rating Scale describes the spectrum of deformities seen after massive weight loss, with most patients exhibiting the more severe grades. This scale was designed to classify postbariatric deformities, in recognition that the standard ptosis grading scale was not descriptive enough to characterize the unique changes in breast shape that occur in this population. The least severe deformities involve grade I or II ptosis or macromastia. The midrange deformities (Pittsburgh Scale severity of 2 out of 3) demonstrate grade III ptosis and can still be treated with traditional breast-reshaping techniques. The most severe deformities (Pittsburgh Scale severity of 3 out of 3) have one or both of the findings unique to the massive-weight-loss patient: severe volume depletion with a flattened breast shape and/or a prominent lateral roll of skin and fat that merges the breast mound with the upper back tissues. Additionally, in any patient who has undergone massive weight loss, the nipples may be medialized. Failure to recognize this finding and move the nipples laterally along a true breast meridian is a pitfall of breast reshaping in massive-weight-loss patients.

Grading Scale for Severity of Breast Deformities After Weight Loss

Severity Grade	Deformities Noted	Recommended Treatment
0	Normal	Normal
1	Ptosis grade I or II or severe macromastia	Traditional mastopexy (with preference for vertical technique), standard breast reduction techniques, or implant augmentation ± elevation of nipple through limited mastopexy scars
2	Ptosis grade III, moderate volume loss, or constricted breast	Traditional mastopexy (often requiring Wise pattern) Consider implant augmentation to accompany mastopexy
3	Severe lateral roll and/or severe volume loss with loose skin	Parenchymal reshaping techniques with dermal suspension Consider autoaugmentation Avoid implant augmentation if existing volume will create a reasonable result

The changes in breast shape after weight loss, in the most severe form, are characterized by two findings that pose significant technical challenges. The first finding is volume loss with a stretched skin envelope and flattening of the breast against the chest wall.

The second finding is a roll of skin and fat on the lateral border of the breast extending onto the chest wall. This roll of skin and fat obscures the lateral curve of the breast, an important aesthetic unit. The technique of dermal suspension and selective autoaugmentation described in this chapter can correct these deformities and restore breast shape by using available parenchyma to build projection and recruiting the lateral chest wall tissue into the breast mound. In any massive-weight-loss patient, the surgeon must also be aware that the nipple position may be abnormally medial and should be repositioned along a true breast meridian.

Preoperative Assessment

In evaluating any massive-weight-loss patient, the surgeon should take a detailed history, including the type of weight-loss surgery, time since the surgery, and the patient's starting and current BMIs. The patient should be as close to goal weight as possible and at a stable weight, no more than a 2 kg (5-pound) change per month, for 3 months. This weight stabilization often occurs 12 to 18 months after gastric bypass. For a patient with a BMI over 35, the surgeon should consider referring the patient back to the weight-loss specialists to optimize her diet and exercise programs and optimize the BMI.

Physical examination of the breast should include a careful search for masses. Parenchymal volume should be assessed, along with the presence and size of a lateral roll of skin and fat. The surgeon should determine whether the native breast parenchyma and lateral roll together would provide adequate volume for a breast reshaping procedure. Prior scars should be noted and considered in terms of their impact on blood supply in the selected procedure. Mammography is performed in accordance with the American Cancer Society guidelines.

Preoperative Planning

Choice of Technique

Many procedures have been described for correction of the breast deformities seen in massive-weight-loss patients. The severity of each of the above-mentioned deformities, the preferred breast size of the patient, and the surgeon's experience will all influence the type of procedure offered. Each patient is unique and the chosen procedure must not only address each aspect of the breast deformity, but it must be able to deliver the size and shape that the patient desires.

Excessive Breast Volume (Pittsburgh Grade 1)

Some patients, despite massive weight loss, maintain significant breast volume despite varying degrees of ptosis. Patients who desire to be smaller than their current size will require a breast reduction. Although short-scar techniques have increased in popularity, the skin redundancy and poor skin elasticity will result in a large inferior dog-ear that will require horizontal excision. The pitfall of the short-scar technique in these patients would be to chase the dog-ear inferiorly. This would leave an unsightly scar below the inframammary fold. A predictable shape and size can be

achieved using a Wise pattern skin excision. This excision will often need to be carried out laterally onto the breast to excise redundancy in this area. A medial or inferior pedicle can be used depending on the nipple to fold distance and the experience of the surgeon. Due to the medial positioning of the nipple in many patients who have undergone massive weight loss, it may be difficult to get adequate nipple rotation if a medial pedicle is chosen. This must be given consideration in the preoperative planning. Liposuction of the lateral fold can also be a useful adjunctive procedure to assist in contouring the lateral fold of the breast.

Inadequate Breast Volume (Pittsburgh Grades 1 or 2)

Patients who have experienced significant breast involution as a result of massive weight loss will require breast implants if larger breasts are desired and a prominent lateral chest roll is not available to recruit into the breast mound (see next section). This autologous augmentation is almost always a better choice than implant augmentation. Young patients who have good skin tone can be considered for an isolated breast augmentation. In patients where there is excessive skin redundancy or an enlarged nipple-areola complex, a concomitant mastopexy may be necessary. In complicated cases where there is significant asymmetry or a loose inframammary fold, a staged mastopexy-augmentation may be necessary to achieve the best aesthetic outcome.

Adequate Breast Volume and Severe Changes (Pittsburgh Grade 3)

The majority of patients who have undergone massive weight loss present with significant breast ptosis and skin redundancy but maintain adequate breast volume. Even if the native parenchyma appears to have reduced volume, the lateral skin and fat roll adjacent to the breast mound, when added to the existing parenchyma, can create adequate size. During the consultation these patients often state that they want a breast reduction because of the significant skin redundancy and ptosis, when in reality they require a mastopexy. The parenchymal volume is often sufficient to achieve a good size and shape, but there is rarely much to spare. During the physical examination, the surgeon must determine whether there is adequate breast volume and whether there is a lateral skin roll with sufficient volume. For patients with sufficient parenchymal volume, severe ptosis, and a lateral skin fold, we recommend dermal suspension of the breast tissue to the chest wall with parenchymal reshaping and autoaugmentation from the lateral skin roll. In difficult cases, where there is significant asymmetry, the smaller breast can be augmented using autologous tissue to match the larger breast. If the autoaugmentation is not sufficient, the larger breast may need to be reduced to match the smaller breast.

The surgical plan is as follows:

- Mark with a Wise pattern, encompassing the lateral roll of tissue.
- Deepithelialize the entire Wise pattern area.
- Deglove the breast parenchyma.
- Elevate the medial and lateral parenchymal flaps.
- Suspend the dermal edge of flaps to rib periosteum.
- Plicate the dermis to shape the breast.
- Place sutures along the lateral edge of the breast to define its curvature.
- Redrape the skin.
- Release any dermis that is tethering the nipple.
- Close the skin.

Markings

The incision design is based on an extended Wise pattern that preserves both the inferior and central pedicle. The midline, inframammary fold, and sternal notch are marked as in traditional mastopexy. A point 4 to 5 cm from the sternal notch is marked along the clavicle, and a new breast meridian is marked in the position at which the nipple will be placed. This line often lies lateral to the current nipple position as a result of the medialized position of the nipple in a massive-weight-loss patient. The new nipple position is gauged in relation to the inframammary fold and raised 2 cm along the new breast meridian. A keyhole pattern is then drawn, with vertical limbs of 5 cm. The lateral extent of the Wise pattern extends onto the lateral skin roll and is used for breast autoaugmentation. The robust lateral thoracic

perforators allow mobilization of a significant amount of tissue to the breast. Although other authors have advocated the use of tissue that extends onto the back, we often discard the tissue beyond the posterior axillary line because of concerns about vascularity and potential fat necrosis.

Operative Technique

72-1 Dermal suspension mastopexy

A 42 mm cookie-cutter is used to mark the circumference of the new nipple-areola complex. The entire dermis lying within the Wise pattern is deepithelialized. A pedicle base of approximately 10 cm is then marked. The medial and lateral extents of this pedicle are determined by the desired pivot points for the arc of rotation of the medial and lateral flaps. The dermis is scored in all areas except the pedicle base. Flaps 1 to 1.5 cm thick are then raised and the breast is completely degloved down to the pectoralis major fascia. During this dissection, the flaps are constantly monitored to ensure uniform thickness. Dissection continues along the fascia to the level of the clavicles.

Care must be exercised not to release the attachments medially over the sternum, or synmastia may result. Medially, it is important to preserve perforators, including the perforator from the second intercostal artery. The lateral and medial flaps are then elevated down to the chest wall and mobilized. These flaps remain attached to the previously delineated 10 cm central pedicle, which is not undermined. Dissection of these flaps is limited to the minimal amount of tissue necessary to rotate the flaps to preserve the blood supply. These flaps are normally discarded in a traditional inferior pedicle breast reduction.

Once the breast parenchyma is degloved and the medial and lateral flaps are elevated, dermal suspension is performed in a specific sequence, with the patient in a sitting position. The central dermal extension is suspended to the periosteum of the second rib along the new breast meridian with two permanent 0 braided sutures to ensure stability. This is performed by placing the fingers of the non-dominant hand in the intercostal spaces, ensuring safe fixation to the rib periosteum. If the inframammary fold is low or the central dermal extension is short, the central pedicle may need to be suspended to the third rib. The suspension should bring the pedicle and the nipple-areola complex to the desired nipple position. The final decision as to which rib to fixate the parenchyma to is made while the patient is on the operating table.

The lateral breast flap is mobilized and rotated superiorly and medially to shape the lateral border of the breast parenchyma. This flap is commonly fixated to the rib periosteum of the third rib just inferior to where the central pedicle was suspended with two permanent sutures. The size and length of the lateral flap can be reduced to selectively adjust the amount of autoaugmentation to achieve the desired size. The medial flap is then rotated superiorly and laterally to the level of the fourth rib periosteum and fixated in a similar manner. This flap is suspended medial to the new breast meridian to restore superomedial fullness to the breast. It is helpful to redrape the breast skin flaps after each fixation step to confirm that the correct level of dermal suspension has been achieved.

Once the dermal flaps have been suspended to the desired position, the breast parenchyma is shaped using 2-0 braided absorbable sutures. The lateral dermal flap is plicated to the central dermal pedicle first with interrupted sutures, followed by a running overlay suture. This is repeated for the medial flap. In some patients, suturing the dermis of the medial flap to the central pedicle dermis will distort the medial contour. In these cases, the breast parenchyma of the medial flap is sutured to the parenchyma of the central pedicle. Once the desired shape of the lateral and medial breast parenchyma has been achieved, the inferior plication is performed to increase nipple projection. The distance from the inframammary fold to the nipple-areola complex is measured and an inferior plication is performed to set this distance at 5 cm.

Dermal suspension and parenchymal reshaping are both performed with the patient in the sitting position. To minimize asymmetry, each of the previously outlined steps is performed sequentially on both breasts. The patterns of plication cannot be predicted preoperatively; adjustments must be made intraoperatively to achieve the desired shape. Additional rows of plication may be required. The surgeon should be satisfied with the shape of the parenchyma while the patient is on the operating table and should not leave the operating room if he or she is not happy with the dermal plication and the breast shape and projection after skin flaps are redraped. If the shape is not optimal, removal of previous plication sutures or further plication is necessary.

To further define the lateral sweep of the breast, the dermis of the lateral flap is secured to the serratus fascia. In addition to defining the lateral border of the breast, these sutures help increase nipple projection and minimize the risk of lateral herniation of the breast parenchyma. The lateral flap is not fixated to the rib periosteum to avoid potential injury to the long thoracic nerve and the thoracodorsal vessels and nerve.

The breast flaps are redraped, and the final breast shape and projection are assessed. Closure begins with a half-buried 2-0 polypropylene suture that secures both breast flaps in an inverted-T fashion to the inframammary fold. This is tied over an iodine-impregnated petrolatum gauze bolster to protect the skin and is left in place for 1 week. The remainder of the skin is temporarily reapproximated with staples. The vertical limb is closed in two layers with absorbable sutures, and the horizontal incision is closed with a running deep dermal suture. One drain is draped around the pedicle before closure and is brought out laterally through the incision.

The nipple-areola complex is occasionally tethered by the dermis and requires release to bring the nipple to the proper position. If this is not performed, the nipple may have a retracted appearance postoperatively. Because of the robust blood supply from the pedicle, the dermis around the areola may be safely scored halfway around its circumference. The nipple-areola complex is secured to the skin flaps with an absorbable suture in one layer. Cyanoacrylate glue is used along all suture lines to seal the incisions.

Postoperative Care

Gauze fluffs are placed over all incisions, and the chest is wrapped with an elastic (Ace) wrap until the first postoperative visit. The drains are removed when the output is less than 30 ml per day. The bolster stitch is also removed during this visit. Patients are instructed to wear a sports bra for 6 weeks to allow complete healing of all incision lines. We recommend the use of a sports bra that has a zipper in the front for patient comfort. The patient is instructed to minimize strenuous activity and not to lift anything greater than 4.5 kg (10 pounds) for the first 3 weeks, after which activity can slowly increase. Patients can begin wearing an underwire bra at 6 weeks postoperatively.

This procedure can be performed on an outpatient basis if no other procedure is performed at that time. If it is combined with other body-contouring procedures, we often keep the patient overnight in the hospital.

Combined Procedures

Patients who present for body contouring after massive weight loss often have multiple anatomic areas that they want corrected. The technique of mastopexy with dermal suspension and autoaugmentation can be combined with other body-contouring procedures in selected patients. Many patients request combined mastopexy with abdominal recontouring. For these women, the abdominal recontouring procedure should be performed first. Because the abdominal recontouring procedure will lower the inframammary fold, intraoperative adjustments may need to be made to the inferior line of deepithelialization before the mastopexy is performed. Similarly, if a fleur-de-lis abdominoplasty is to be performed, the inframammary fold may also be rotated medially, and the markings may require adjustment. In patients with loose inframammary folds, we consider deferring the mastopexy to a second stage to achieve the best aesthetic outcome.

This technique can easily be combined with either an upper body lift or with brachioplasty. When it is performed in combination with an upper body lift, the markings from the upper back lift will blend into the lateral skin roll excision for the mastopexy, leaving a single incision line. The lateral flap for the mastopexy is marked as usual and extends no farther than the posterior axillary line. The patient is positioned prone, and the upper back lift is performed first. The patient is then turned to the supine position for the mastopexy. The lateral incision of the mastopexy is then closed with no dog-ears by blending it into the upper back incision. When combining a mastopexy with brachioplasty, we attempt to merge the caudally directed axillary incision of the brachioplasty with the lateral incision of the mastopexy. We try to avoid an inverted-T point in the axilla if possible. The patient should be informed that there may be redundancy at the posterior axillary line that can be corrected with an upper body lift at a later time.

Fat grafting has recently become a popular technique for soft tissue augmentation. However, fat grafting has little role in the primary correction of breast ptosis resulting from massive weight loss. Once a patient has completely recovered from mastopexy with dermal suspension and parenchymal reshaping, fat grafting may be useful to correct any contour deformities or areas in which more fullness is desired. It could be a useful ancillary procedure in patients with significant skin redundancy and insufficient breast volume who desire a larger breast size without using implants. In these select cases, the patient may benefit from a two-stage procedure in which she undergoes a dermal suspension mastopexy in the first stage, followed by fat injections in a second stage to augment breast size.

Problems and Complications

This technique has proved very safe and reliable. Complications include hematoma (less than 1%), seroma (less than 3%), and minor wound dehiscence at the T point (5%). The generous central pedicle blood supply, combined with the increased vascular network within the pedicle that is so commonly observed in weight-loss patients, helps prevent nipple loss. In fact, we have had no nipple necrosis in more than 120 dermal suspension mastopexy cases.

Wound dehiscence at the vertical incision and/or triple point is managed with debridement and gauze dressings in an office visit. These have all healed well with conservative measures. We routinely place a half-buried 2-0 polypropylene suture at the T point and remove this in the office 5 to 7 days postoperatively. This helps reinforce the closure at that juncture.

Seromas have been observed in the lateral region of the breast after drain removal and have all been treated with needle aspiration in the office. None has required reoperation.

One must always be wary of fat necrosis at the distal end of any transposed flap. We have not observed this in the lateral chest wall flap used for autologous augmentation, but we take several measures to avoid this complication. First, the lateral extent of the flap is limited to the region of the posterior axillary line. We do not extend this flap onto the midback. Second, the edge of the flap is checked for signs of arterial bleeding. Third, we exclude active smokers.

Results

This 40-year-old woman with a BMI of 33.8 lost 61 kg (135 pounds) before surgery. The lateral view of the surgical markings demonstrates an important point in the preoperative planning of this operation. The resection required to capture the lateral skin fold can extend beyond the tissue within the Wise pattern used for autologous augmentation. This flexibility allows the skin lateral skin envelope to be adequately contoured, with adjustment of the amount tissue mobilized to the breast. The results are seen 7 months postoperatively.

This 49-year-old woman lost 74 kg (163 pounds) after a laparoscopic gastric bypass procedure. Her BMI at the time of surgery was 27. She had significant preoperative asymmetry. By selectively resecting the breast parenchyma and by using lateral fold flaps of different volumes, postoperative symmetry can be dramatically improved. She is shown 1 year postoperatively.

This 37-year-old patient with a BMI of 22.6 had lost a total of 62 kg (136 pounds). She had a small breast volume with no true lateral skin fold. Despite these findings, the procedure allowed very good control of the skin envelope and parenchymal re-shaping. She is shown 18 months postoperatively.

This 42-year-old woman with a BMI of 25 underwent a combined fleur-de-lis abdominoplasty and mastopexy. To prevent running the incision onto the chest, we stopped the incision at the xyphoid process. Four months after her initial procedure, the patient was left with a small dog-ear at the cephalad aspect of the fleur-de-lis incision. If a dog-ear remains 3 months postoperatively, we excise it in the office with the patient under local anesthesia. By waiting, we can minimize the cephalad extension of the scar. The patient is shown 4 months postoperatively (before the dog-ear excision) and at 7 months from her initial procedure.

Breast Reduction in Massive-Weight-Loss Patients

In a massive-weight-loss patient with ptosis and adequate or excessive parenchymal volume, a good option is breast reduction with a Wise pattern skin resection in conjunction with a traditional or extended medial pedicle. The Wise pattern allows resection of excess skin and precise control of the dermal envelope. The vascularly robust medial pedicle provides a pleasing medial curve to the breast shape and allows excellent repositioning of the nipple-areola complex. Upper pole fullness may be achieved by parenchymal elevation with suturing to the rib periosteum or pectoralis fascia. A decrease in the amount of pseudoptosis or bottoming out is an added benefit. Small to large parenchymal resections are possible, and the added benefit of familiarity of technique with most surgeons makes this an appealing alternative in massive-weight-loss patients.

This 56-year-old woman with a BMI of 29.5 after weight loss induced by lifestyle changes alone (no gastric bypass) manifested macromastia, severe ptosis, and moderate lateral chest skin excess. True macromastia is uncommon in weight-loss patients. These cases can be managed with a Wise pattern and medial pedicle to support the nipple. The medial pedicle, once rotated, helps maintain medial fullness and projection. Approximately 550 g of breast tissue was removed from each breast. The patient is shown 6 months postoperatively.

Concluding Thoughts

Following massive weight loss, patients often have sufficient breast volume to achieve an aesthetic shape. Dermal suspension with parenchymal reshaping and selective autoaugmentation is a versatile technique that enables the surgeon to effectively address the major breast deformities seen in the massive-weight-loss patient.

Clinical Caveats

When combining these cases with abdominal contouring cases, the abdominal procedure should be performed first. The inframammary fold will often be lowered, and the mastopexy markings may need to be adjusted superiorly.

A thickness of 1 to 1.5 cm should be maintained on the skin flaps to both improve contour, as well as to minimize tissue loss at the inverted-T point.

Preserving the second intercostal perforator medially will ensure a good blood supply to the overlying skin-parenchymal envelope.

The surgeon should not leave the operating room if he or she is not happy with the dermal plication, appearance of the breast shape, and projection after the skin flaps are redraped. If the shape is not optimal, removal of previous plication stitches or further plication will be necessary.

The dermis around the nipple-areola complex can be partially released around its circumference to allow it to be easily transposed to the keyhole pattern without tension. Failure to do so may result in a retracted nipple.

Annotated Bibliography

Graf RM, Mansur AE, Tenius FP, et al. Mastopexy after massive weight loss: extended chest wall-based flap associated with a loop of pectoralis muscle. *Aesthetic Plast Surg* 32:371-374, 2008.

The authors describe their experience with a simple and reliable mammoplasty technique using an extended thoracic wall flap associated with a loop of pectoralis muscle that results in a pleasing breast shape and long-lasting results.

Hamdi M, Van Landuyt K, Blondeel P, et al. Autologous breast augmentation with the lateral intercostal artery perforator flap in massive weight loss patients. *J Plast Reconstr Aesthet Surg* 62:65-70, 2009.

The authors present their experience with the lateral intercostal artery perforator (LICAP) pedicled flap for breast autoaugmentation in the massive-weight-loss patient. This tissue provides volume for breast augmentation and improves the lateral thoracic contour by removing excess skin.

Hurwitz DJ, Agha-Mohammadi S. Postbariatric surgery breast reshaping: the spiral flap. *Ann Plast Surg* 56:481-486, 2006.

The authors discuss the evolution of a technique useful for breast reshaping using the spiral flap and upper body lift to produce comprehensive, effective, and safe contouring of the breast and upper torso in massive-weight-loss patients.

Kwei S, Borud LJ, Lee BT. Mastopexy with autologous augmentation after massive weight loss: the intercostal artery perforator (ICAP) flap. *Ann Plast Surg* 57:361-365, 2006.

The authors present their experience with a pedicled fasciocutaneous flap based on the intercostal artery perforators (ICAP) to correct breast ptosis, restore breast volume, and eliminate upper trunk tissue excess.

Losken A, Holtz DJ. Versatility of the superomedial pedicle in managing the massive weight loss breast: the rotation-advancement technique. *Plast Reconstr Surg* 120:1060-1068, 2007.

The authors describe a technique that uses the superomedial pedicle, a versatile, well-vascularized pedicle that allows glandular plication of the lower pole with concomitant autoaugmentation of the superior pole of the breast. This method, used to recontour the breast following massive weight loss, includes parenchymal shaping through plication as well as suspension. Medial advancement of the lateral breast skin on closure redefines the lateral breast and eliminates the lateral breast roll.

Rubin JP. Mastopexy in the massive-weight-loss patient: dermal suspension and total parenchymal reshaping. *Aesthetic Surg J* 26:214-222, 2006.

A technique of dermal suspension and total parenchymal reshaping is presented that eliminates the lateral axillary roll deformity while using this tissue to autoaugment breast volume. The procedure is safe, reliable, and has a low complication rate. It produces a pleasing and youthful breast contour and allows great control over skin envelope and parenchymal shape.

Rubin JP, Gusenoff JA, Coon D. Dermal suspension and parenchymal reshaping mastopexy after massive weight loss: statistical analysis with concomitant procedures from a prospective registry. *Plast Reconstr Surg* 123:782-789, 2009.

Evaluation of the outcomes of the authors' mastopexy techniques after massive weight loss is presented; they conclude that the technique is a safe, effective, and durable method for treating this complex breast deformity.

Rubin JP, Khachi G. Mastopexy after massive weight loss: dermal suspension and selective auto-augmentation. *Clin Plast Surg* 35:123-129, 2008.

A versatile technique is presented for restoring an aesthetic, youthful breast shape in massive-weight-loss patients; the procedure produces overall low complication rates. Despite the disadvantages of a lengthy scar and the increased operative time required for deepithelialization, this technique provides a high rate of patient satisfaction.

Song AY, Jean RD, Hurwitz DJ, Fernstrom MH, Scott JA, Rubin JP. A classification of contour deformities after bariatric weight loss: the Pittsburgh Rating Scale. *Plast Reconstr Surg* 116:1535-1544; discussion 1545-1546, 2005.

The authors present a validated measure of contour deformities after bariatric weight loss, with clinical applications in preoperative planning and evaluation of surgical outcomes.

CHAPTER 73

Management of Breast Asymmetry

GLYN JONES

Breast asymmetry is a distressing condition that carries significant implications for patients in terms of psychosexual impact. It also presents daily functional difficulties with the fit of clothing. The causes are usually developmental but may also be iatrogenic. Correction involves surgical intervention and may require a staged approach in more complex deformities.

Indications and Contraindications

To understand the indications for corrective surgery in breast asymmetry, one has to appreciate the plethora of causes of asymmetry in both the female and male breast.

Causes of Breast Asymmetry

Developmental Causes

1. Developmental hypoplastic breasts
2. Tuberous, constricted breast deformity
3. Poland's syndrome
4. Gynecomastia

Iatrogenic Causes

1. Asymmetrical breast reduction
2. Incorrect implant positioning during augmentation mammoplasty
3. Consequences of capsular contracture
4. Effects of breast reconstruction
5. Effects of radiation after breast conservation

This list provides a working classification of breast asymmetry. All of these categories constitute potential reasons to operate for asymmetry. However, contraindications to surgery are relative and include the following:

1. Body dysmorphic disorder
2. Severe psychiatric illness
3. Poor general health (breast procedures are elective and can be delayed)
4. Active smoking
5. Metastatic disease

Pertinent Anatomy

The anatomy of the breast has already been covered, but a few points bear reiteration. Correction of breast asymmetry centers on re-creation of symmetrical lower poles and good upper pole fullness and symmetry. An abnormally placed inframammary crease must be corrected to achieve symmetry. If the breast base is abnormal, the aesthetic outcome will be unsatisfactory. The tight inframammary fold associated with a constricted or tubular breast is tightly contracted. Correction involves release of the fibrous developmental band using radial scoring along the crease. This must be done up to the dermis to be completely effective, allowing expansion of the lower pole of the overlying breast tissue. Care should be taken to note and mark the correct natural crease position. The uppermost extent of the gland should be marked, and the surgical plan to correct deficiencies will involve implants, flaps, or fat injection. These two sets of maneuvers will go a long way toward correcting the appearance of the asymmetrical breast.

In addition, the contour of the underlying chest wall and sternal contour should be noted, because conditions such as Poland's syndrome or pectus excavatum can require larger than expected implant volumes to correct hypomastia. The level and degree of development of the nipple-areola complex are also essential to the creation of a symmetrical result. Even if the underlying breast mound has been perfectly matched, an asymmetrical nipple level will mar the aesthetic outcome dramatically.

Preoperative Assessment

Patients should be evaluated after taking a careful developmental history with specific reference to age of menarche and thelarche. Patients should be asked about upper extremity development and function. During the examination it is also helpful to attempt to form an impression of the patient's psychological maturity, particularly when surgery is proposed on younger women and teenagers; parental and peer pressure should be evaluated as a factor. Clinical examination involves assessment of breast, chest wall, and upper extremity development to exclude congenital problems, such as Poland's syndrome. The level of the inframammary creases and their de-

gree of tightness should be evaluated carefully. Nipple size, level, and the degree of development are noted. Measurements include nipple-to-notch and inframammary fold-to-nipple distances as well as pinch thickness tests to evaluate the thickness of available breast tissue in all quadrants of the breasts. Pectoralis major muscle bulk, thickness, and function are also worth assessing. The presence of pectus excavatum or carinatum can have an impact on the nature and success of a reconstructive attempt. Autologous fat donor sites on the abdomen and hips should be evaluated.

Preoperative Planning and Operative Technique

Management of Developmental Breast Asymmetries

Many women develop minor breast asymmetry during otherwise normal pubertal breast growth. It is not uncommon to see a young adult woman with one nipple slightly higher than the other or the lower pole of one breast slightly lower than the opposite side. These minor discrepancies are insignificant to most patients, and correction would require breast scarring, which is rarely justified, given the subtlety of the deformity. In other patients, however, the discrepancy in breast volume may approach one or even two bra cup sizes. These deformities are embarrassing for the patient and can lead to psychosexual problems in adult life as well as during puberty, when insensitive comments from peers during gym and sports activities can lead to social withdrawal. While catch-up growth may occur in the early to mid-teen years, it is rare in my experience to see a severely lagging hypoplastic breast achieve acceptable symmetry in the late teens to early adulthood. It is my preference to defer surgical intervention until after the patient is 18 years of age, but occasionally a severe deformity mandates earlier surgery.

Asymmetrical Hypoplasia

Developmental hypoplasia may range from mild to severe and can be unilateral or bilateral. In one sense, a bilateral deformity can be easier to correct, because it allows the surgeon the luxury of operating on both breasts to achieve a symmetrical outcome, particularly when implants are being used.

This 36-year-old woman developed severe breast asymmetry in her teens. She had a constricted hypoplastic right breast and a ptotic, almost tubular left breast. She requested breast augmentation. An asymmetrical breast augmentation with overlying mastopexy was performed. A 325 cc implant was placed on the right side with periareolar mastopexy, and a 250 cc implant was placed on the left side with a vertical mastopexy. The patient was delighted with the early postoperative outcome.

Unilateral Hypomastia With a Normal Contralateral Breast

Unilateral hypomastia requires augmentation of the hypoplastic breast to achieve volume symmetry. If ptosis is an additional component, mastopexy augmentation is indicated. Hypoplastic breasts often have an element of lower pole constriction that, if not corrected, will lead to a double-bubble deformity developing postoperatively. Every effort should be made to recognize and correct this problem at the initial operative procedure. Correction can be challenging and involves serial radial scoring along the tight inframammary crease to allow it to expand laterally over the implant curvature. These scoring incisions are passed through the fat up to the dermis, taking care not to burn the dermis with cautery. Cuts should be placed every centimeter along the old inframammary crease until the deformity is eliminated. The downside of performing these radial incisions is that they increase the likelihood of implant palpability in the lower pole. Inflatable, disposable implant sizers are extremely useful in assessing final implant volumes for these patients. I usually use a round implant in these cases. An inframammary approach to the subpectoral plane is acceptable if no mastopexy is planned. If a mastopexy is required, it is often relatively minor in extent, and a periareolar approach can provide access for both the augmentation and the required periareolar mastopexy scar. If there is any element of tuberous deformity with herniation of the breast into the areola, this approach provides the optimal exposure for correction. Assessment of patient symmetry in the erect position on the operating table is essential before skin closure.

Tuberous Breast Deformity

Patients with tuberous breasts often have a bilateral problem in that one or both breasts are relatively constricted, with one side larger and more ptotic than the other (see Chapter 63). Breast crease levels may be asymmetrical, with a very short inframammary fold-to-nipple distance present on the more hypoplastic side. The inframammary crease may be very tight and well defined, with clearly visible banding along the fold. Nipple-areolar diameters are often dilated, and the breast may exhibit a tendency to herniate into the areola, further worsening the appearance of deformity. If the larger breast falls within an acceptable size range for the patient, a mastopexy alone may be required on this side. However, if the larger side is also relatively small, it is preferable to perform a mastopexy augmentation on both sides, with a larger implant inserted on the more severely hypoplastic side. A periareolar mastopexy is usually sufficient on the smaller side, whereas a vertical mastopexy augmentation may be mandated on the larger side to help correct some of the glandular ptosis that accompanies the lower pole development on this side. The larger lower pole can be either imbricated or resected to allow a more symmetrical correction compared with the smaller side and its deficient lower pole fill.

It is essential to radially score the tight inframammary creases to achieve an adequate release of the breast tissue and skin over the implants to avoid the troublesome and unsightly double-bubble deformity. As with all mastopexy-augmentation procedures, it is essential to perform the augmentation first before committing to any skin excision. Failure to follow this simple dictum may result in excessive skin resection, creating a tight closure with risk of wound dehiscence or necrosis. I make the initial incision in the lower periareolar quadrant, at the juncture of the areolar-cutaneous junction. Once the implant is in place, tailor-tacking the skin gives a good idea of how much of the areolar skin disk may be safely resected as a periareolar mastopexy. Any vertical resection can be assessed in the same way on the larger, more ptotic side, if necessary.

For implant positioning, it has always been my preference to use the subpectoral plane in primary cases. This allows safe manipulation of the overlying breast tissue during mastopexy without concern for nipple and skin viability. Using this approach, the entire breast becomes the pedicle, because the relationship between the breast gland and the pectoralis major muscle is unaffected.

Poland's Syndrome

Poland's syndrome is a developmental abnormality involving the breast, nipple, and entire upper extremity and shoulder girdle. Typical patients have varying degrees of hypomastia and abnormal nipple-areola complex development, coupled with the absence of the sternal head of the pectoralis major muscle. This may be accompanied by

varying degrees of shoulder muscle hypoplasia as well as symbrachydactyly of the ipsilateral hand. All muscles of the upper extremity are potentially at risk, including the deltoid and less commonly, the latissimus dorsi. The presence and function of the latissimus dorsi should always be tested, because it can be used to reconstruct the ipsilateral anterior axillary fold and the lack of pectoral muscle bulk. Fat injection has recently been offered as an alternative to muscle transposition in less severe cases (see Chapter 63).

Surgery for Poland's syndrome aims to achieve three major aesthetic goals: creation of a breast mound, recreation of the anterior axillary fold, and restoration of the missing infraclavicular fill afforded by the absent sternal head of the pectoralis major muscle. Breast augmentation coupled with either latissimus flap transposition or later fat injection can achieve these goals. If the skin envelope is extremely tight, it can be preexpanded with the use of an integrated valve tissue expander, followed by an expander-implant exchange and latissimus transposition, if indicated.

If athelia exists, nipple reconstruction is also necessary. If the nipple is severely hypoplastic and located too high on the chest wall, it may be preferable to resect the nipple and perform a complete nipple reconstruction *de novo*. If the nipple is correctly placed but merely smaller than normal, soft tissue augmentation with a roll of acellular dermal matrix such as AlloDerm can be placed to increase projection. Tattooing if performed skillfully, can improve the diameter of the areola. If correction is performed in the early to mid teens, the patient and family should be warned that the breast implant will have to be exchanged for a larger one when the patient reaches maturity so that the normally developing contralateral breast can be matched. Patients should also be warned that a ptotic but otherwise normal contralateral breast may require a mastopexy at some point in the future to achieve symmetry. When dealing with Poland's syndrome, the surgeon should recall that the chest wall itself may be less developed and have an unnaturally steep lateral curvature that may make attaining symmetry even more difficult. An implant may tend to slide laterally off the chest wall in such patients, causing the appearance of less anterior projection from the implant than would normally have been achieved. In addition, the sloping chest wall may require a much larger implant volume to be used to compensate for the lack of lateral fill that would be provided by a normal chest wall contour.

Some authors have advocated the use of deepithelialized free flaps, such as a superficial inferior epigastric artery (SIEA) or parascapular flap, as an alternative to latissimus dorsi transposition in an effort to spare as much upper extremity function as possible. Autologous fat injection has also been used with increasing frequency and will probably attain greater significance in the management of this condition as techniques to maintain graft integrity improve (see Chapter 63).

The sternal head of the pectoralis major muscle was absent in this 9-year-old girl, and her nipple was underdeveloped and located abnormally high on her chest wall. Despite her young age, the upper chest deformity was so disturbing to her that correction was indicated, and her family was very supportive of surgical intervention. She is shown 9 years after her initial latissimus dorsi transfer, 7 years after an asymmetrical bilateral augmentation mammoplasty with saline-filled implants. She is now 18 years old, and breast symmetry has remained acceptable.

Courtesy Emmanuel Delay, MD

This 24-year-old woman presented with a moderate degree of Poland's syndrome deformity. Although missing almost all of the pectoralis major muscle, she had moderate breast development, which helped to soften the appearance of the breast deformity. Although a latissimus dorsi transposition and augmentation were certainly a reasonable option for this patient, fat injection was selected as a simpler alternative. A vertical mastopexy was planned to achieve better symmetry with the nonptotic hyperplastic breast. Staged fat grafting was performed, with three procedures involving injection of 260 cc, 350 cc, and 157 cc. Her result is shown at 1 year. Her breasts are now symmetrical, with complete correction of her deformity and a pleasing breast contour.

Gynecomastia

Gynecomastia involves abnormal enlargement of one or both breasts in men. It has two peaks of incidence: the first in puberty and the second in late middle age as male hormone balance changes. Most pubertal cases are idiopathic, but endocrine and chromosomal abnormalities should be identified when present. Obesity is an increasingly common cause of large breast development in males. Young men developing symmetrical, increasing breast enlargement after puberty in the absence of obesity should be questioned about marijuana use, which can stimulate breast growth quite strongly. In older men, the use of medications such as spironolactone should also be investigated. Most older men who develop gynecomastia do so as a result of changing hormone status with age, but breast cancer should be excluded, particularly in unilateral cases in the elderly. The use of systemic steroids can also result in gynecomastia.

Management of gynecomastia in obese patients should focus on weight loss before resorting to surgery. If medications such as spironolactone are the likely cause, their use should be discontinued and alternative medications tried. Once conservative measures have been exhausted, surgery becomes the only option. Many insurance companies do not cover these procedures, because they are regarded as essentially cosmetic in nature.

Surgery usually involves a two-pronged approach incorporating both liposuction and surgical resection. Liposuction is used to contour the chest wall fat peripheral to the enlarged gland; resection of the hypertrophied gland while leaving a small subareolar breast bud improves the central contour. Ultrasound-assisted liposuction has been touted as a successful means of removing both fat and glandular tissue, but I have not found it particularly helpful in dealing with the dense, fibrotic subareolar breast disk. I use power-assisted liposuction for the fatty component and then resect the excess glandular tissue.

Resection is performed through an infraareolar incision. When dissecting beneath the areola, great care should be taken to leave enough subareolar breast tissue in place to prevent the unsightly hollowing that can occur when too much tissue is taken beneath the nipple. This problem creates an extremely unattractive excavated look that is very difficult to correct, because the nipple adheres to the underlying pectoralis muscle and animates with arm motion. I leave a subareolar disk of breast tissue and then bisect the deep gland down to the pectoralis major fascia. Each half of the deeper gland can be resected in turn, which provides easier access than is feasible when performing a monobloc excision. Drains should always be inserted and a

circumferential pressure garment worn in an effort to prevent seroma formation. Ultrasonic liposuction seems to be associated with a higher incidence of seroma than is seen with power-assisted or conventional liposuction. Any resected tissue should always be evaluated histologically to exclude malignancy.

Management of Iatrogenic Breast Asymmetries

Asymmetrical Breast Reduction

The achievement of symmetry during breast reduction is an essential goal of the operation. Underresection or overresection on one side can produce asymmetry that will require subsequent revision. Breast symmetry should always be checked with the patient in the erect position on the operating table before a dressing is applied. Asymmetry caused by a focal problem, such as inadequate resection of the inferomedial or inferolateral quadrants of the breast, can be addressed with minor excisions of both skin and breast tissue with the patient under local anesthesia. Localized liposuction can also be used to address these issues if the breast is more fibrofatty than densely glandular. More gross asymmetries require a re-reduction procedure. Revisionary breast reduction can be a harrowing experience when performed by another surgeon, who may not have access to the original records and an understanding of the pedicle technique used. Generally speaking, if the patient had a Wise pattern reduction performed more than 10 to 15 years previously, it is likely that an inferior pedicled technique was used. Rarely, a superomedial technique may have been used. Vertical scar techniques are usually associated with superior or superomedial pedicles, unless a Hammond short-scar periareolar inferior pedicle reduction (SPAIR) mammoplasty technique was used. It is prudent to leave as much bulk around the pedicle as possible when performing re-reductions, and patients should be carefully counseled about the potential for nipple loss and fat necrosis. Suctioning of the periphery of the breast is usually safe in revisionary reduction, and skin laxity resulting from suction should be tightened by excision as needed. Stretched nipple-areolar diameters can be reduced, but this should only be done at the end of the procedure, because tension on the periareolar skin inset is often tighter than anticipated in re-reduction procedures. In thin-skinned patients, a Gore-Tex periareolar purse-string suture, as described by Hammond, is very useful in limiting skin stretch postoperatively.

Asymmetry Resulting From an Augmentation Procedure

Implant insertion for breast augmentation can lead to asymmetry, usually as a result of a failure to recognize and correct a preexisting asymmetry, or asymmetrical implant placement and overdissection of an implant pocket on one side.

73-1 SPAIR
mammoplasty
technique

Preexisting asymmetry requires the use of a larger implant on the smaller side and a smaller implant on the larger side. This may be more easily achieved with saline implants, which allow minor intraoperative adjustments to achieve as near perfect a result as possible. However, asymmetry may also arise when implants are placed in overdissected pockets, most commonly superior or inferolateral overdissection. Excessive upward dissection toward the clavicle creates abnormal fullness in the infraclavicular area, creating a top-heavy appearance to the breast. This is a particular risk of closed transaxillary augmentation, where inadequate release of the lower pole attachments of pectoralis major can displace the implant superiorly. The use of the endoscopic approach has alleviated this tendency considerably. Correction can be performed with an endoscopic transaxillary release of the lower pole, which allows the implant to settle in a more inferior position.

Overdissection of the inferomedial pocket allows the implant to bulge into the axilla, but what is more important, it creates an unattractive double-bubble appearance as the implant bulges beyond the lateral breast crease. Correction is extremely difficult, because the breast skin needs to be tacked down to the serratus fascia or muscle, all the while facing the outward force of a large implant being squeezed laterally by an active pectoralis major muscle. Fixation sutures of a nonabsorbable material such as 2-0 or 0 Mersilene or Ethibond can be useful, but the tendency to tear through with failure of the repair is high. Recently the use of a Strattice inlay anchored to the serratus muscle deeply and to the breast tissue and skin more superficially has met with better success. Another approach is advancement of an inferior skin flap, which can be tacked to the serratus muscle deeply; the overlying lateral breast crease skin is then sutured to the advanced skin, similar to the Ryan approach used in breast reconstruction. The attachment of skin to skin provides a more stable support mechanism than sutures between tenuous breast fat and serratus muscle. Avoiding this problem is definitely preferable to necessity of subsequent attempts at repair.

Overdissection of the medial breast pocket creates the potential for synmastia, an extremely unattractive deformity that is very difficult correct. Acellular dermal matrices have found an immensely useful role in this area: they provide a strong suturable material that, once incorporated and vascularized, can provide a firm barrier to subsequent implant migration medially. The procedure is combined with a suture plication capsulorrhaphy reinforced with Strattice or AlloDerm.

This patient presented with breast asymmetry and recurrent ptosis after a mastopexy-augmentation performed 5 years previously. Her right nipple was significantly lower than the left, and the right implant was higher than the left. A right open capsulotomy was performed to lower the implant on the right. An asymmetrical mastopexy was performed, raising the right nipple more than the left to achieve symmetry. The patient is shown 2 months after revision surgery.

This 34-year-old woman with hypomastia and ptosis had a subpectoral breast augmentation with saline-filled implants. The patient was concerned that her breasts were not large enough, and she had a clear double-bubble deformity on the left side. This was worsened by pectoral muscle action. The patient was advised to have an implant exchange to a larger size with subglandular conversion. The problem was corrected completely with this approach, and the patient is shown postoperatively with a symmetrical result.

This young woman had undergone transaxillary endoscopic breast augmentation with saline-filled implants. She was referred to me for correction, complaining of excessively high-riding implants. Clinically her implants had been placed too high, with at least 60% of the implant volume lying above the equator of the breast. Through the original transaxillary incision, I performed an inferior capsulotomy, allowing the devices to be placed into a more natural position. She is shown in the early postoperative period with a more acceptable aesthetic appearance of her breasts.

Asymmetry From Capsular Contracture

Capsular contracture is the single most common complication of breast augmentation. As the condition deteriorates, contraction causes increasing deformation of the augmented breast. Grade III and IV contractures may pull the implant into an abnormal position, displacing it in almost any direction and causing the shape of the implant to change from a teardrop to a more globular form on the chest wall. The net result of these compressive forces is breast asymmetry that deteriorates over time. Surgical intervention is the only means of correcting the deformity.

Closed capsulotomies are no longer performed; they have given way to open procedures. A capsulotomy with implant exchange, or better still, total capsulectomy with implant exchange, has become the mainstay of treatment. Once an established capsule has created a deformity, a recurrence is more like with a capsulotomy than with a capsulectomy. Capsulectomy provides the surgeon an opportunity to allow a fresh implant to generate a new capsule around the device, in the process adjusting the pocket position and size as required to achieve a more aesthetic result. If needed, acellular dermal matrices such as AlloDerm can be incorporated into the procedure; it is becoming apparent that this material may limit the formation of a purely fibrous capsule within the area in which it is placed. The high elastin content of human dermis in this biologic mesh is possibly partially responsible for the elastic nature of the capsule, as is the lack of cellular inflammatory response that is seen in the usual fibrous capsules forming around breast implants.

In addition, if a patient has a gel-filled implant associated with severe capsular contracture, this can be exchanged for a saline-filled device in an attempt to minimize recurrence. The addition of a textured surface may also help mitigate the capsular response, although at the expense of potentially increased palpability and wrinkling of the implant beneath the skin.

Fat injection is also showing promise as a means of softening the periprosthetic capsule, although data are still limited (see Chapter 65).

Effects of Breast Reconstruction

Breast reconstruction, particularly when performed unilaterally, may result in considerable asymmetry, particularly when implant reconstruction is performed. It is not within the scope of this chapter to cover all of the options available to achieve symmetry in breast reconstruction. Bilateral implant-based reconstructions tend to achieve a higher degree of symmetry because both breasts are shaped by an identical implant, often with the assistance of acellular dermal matrices placed at the time of the initial mastectomy and implant insertion. Unilateral implant reconstructions, however, often require adjustment of the opposite breast in the form of a mastopexy/augmentation or reduction, depending on the size and shape of the breast before mastectomy. In addition, fat injection has proved to be a powerful tool in helping shape the upper pole of the reconstruction, where implants often fail to achieve adequate volume fill. Autologous reconstructions have the potential to achieve greater symmetry without having to adjust the contralateral breast, because large quantities of skin and fat are available for shaping the reconstruction.

This elderly woman had undergone a right mastectomy for breast cancer 10 years earlier, with immediate expander-implant reconstruction. She developed capsular contracture around the high-riding implant, with severe acquired breast asymmetry. She was then diagnosed with a new left breast cancer requiring mastectomy. Treat-

ment involved immediate implant insertion, with AlloDerm coverage of the lower pole. On the right side, an open inferior capsulotomy with capsulorrhaphy to the upper pole of the implant pocket was performed. This allowed inferior placement of the implant into a more anatomic position. Shape and symmetry were vastly improved; the patient declined nipple reconstruction.

Effects of Radiation After Breast Conservation

Radiation is a powerfully negative force influencing breast shape after reconstruction of breast-conserving therapy. Breast-conserving therapy has been shown to be associated with deteriorating breast aesthetics over time; patients with larger breast volumes develop the most serious retraction, fibrosis, and fat necrosis when compared with women with smaller breasts. In addition, the deformity caused by the lumpectomy itself can also deteriorate with the addition of radiation therapy. To ameliorate these consequences, oncoplastic reduction plays an increasingly important role in treating patients undergoing breast-conserving therapy. Once the deformity is established, however, complex reshaping of the irradiated breast is the only means available to correct the asymmetry.

Correction of a breast-conserving therapy–induced breast deformity after radiation has been delivered involves the movement of breast flaps damaged by ionizing radiation. This results in compromised blood flow to the tissues and decreased tissue compliance from radiation-induced fibrosis and edema. Irradiated flaps do not move as well or as far as nonirradiated flaps, and seroma formation and infection rates are all increased in radiated beds. If edema is still resolving after radiation, I prefer to wait at least 3 to 6 months so that with massage and compression therapy, edema will be reduced. Referral to a lymphedema specialist can often expedite this process. Softer flaps are more pliable and move far easier than stiff, edematous tissues do.

Extreme caution should be exercised when dealing with such patients, and undermining of irradiated skin should be kept to a minimum. Skin necrosis is much more common after radiation therapy because of the reduction in cutaneous blood flow that accompanies the treatment. It is preferable to lift and/or reduce the contralateral breast to match the smaller irradiated side and keep tissue redistribution on the irradiated side to a minimum. In severely asymmetrical radiation-damaged breasts, it may be necessary to perform a completion mastectomy with immediate autologous reconstruction rather than attempt to reshape compromised, poor-quality local tissue. This may achieve a volume and shape match similar to the contralateral side. Alternatively, a contralateral balancing procedure may be necessary to match the reconstructed breast as a secondary procedure.

This 60-year-old woman presented 6 years after a right lumpectomy and radiation therapy for breast cancer. She had developed severe breast asymmetry and requested improvement without resorting to extensive flap procedures. The right breast was stiff and fibrotic, with lower pole edema. Treatment involved a left vertical breast reduction and a very conservative periareolar mastopexy to elevate the right nipple into a more acceptable position without extensive undermining. Although postoperatively her symmetry is not perfect, she is very happy with the outcome, achieved through a conservative outpatient procedure with minimal risk to the irradiated side.

Postoperative Care

The postoperative management of these patients varies enormously, depending on the nature of the deformity and the procedure required for correction. It is beyond the scope of this chapter to detail all of these procedures; see the appropriate operative descriptions in other chapters for this discussion.

Postoperative management involves the careful support of implants in their correctly placed location and may require the use of external taping or bras to assist with this process. Careful preoperative counseling and preparation for the possible need for revisions must be clearly explained to the patient to avoid postoperative disappointment, particularly with severe congenital deformities or radiation-induced asymmetry, both of which can be particularly challenging to correct.

Problems and Complications

Breast asymmetry surgery generates the same spectrum of risks and complications as the component operations used to correct the deformities. Congenital anomalies such as constricted, tubular breasts run the increased risk of double-bubble deformity if the original crease is not fully expanded and obliterated to make way for a new one. The position of the new crease must be placed accurately to match the contralateral normal position. Similarly, overdissection of the new crease position will result in an extremely unattractive bulge of the implant beyond the desired breast crease level, and such a deformity is extremely difficult to correct. A capsulorrhaphy is necessary between the breast capsule and the correct position on the chest wall, but the tissues are thin and hold sutures poorly, easily tearing through when a large implant exerts pressure against the repair. The use of a piece of acellular dermal matrix, such as AlloDerm or Strattice, is helpful in providing a more robust material to anchor such a repair.

Revision surgery for breast asymmetry requires operating in a previously scarred bed. The use of breast pedicles in such situations or raising scarred or radiated skin flaps may result in skin and fat necrosis or nipple loss. Every effort must be made to maintain blood flow to tissues by ensuring thick, broad-based pedicles and thicker flaps than might otherwise be used.

Outcomes

Breast asymmetry surgery is often difficult and may require revisions. Given the wide range of deformities and the spectrum of procedures required to correct them, it is almost impossible to provide outcomes data for this subset of clinical conditions.

Concluding Thoughts

Breast asymmetry is a distressing to the patient and carries a potentially profound psychological impact. The treatment of an established deformity requires the use of a broad range of procedures and techniques to attempt to restore a close facsimile of the normal breast from a less than ideal foundation. Achieving good results in these patients taxes the ability and skills of even the best surgeons and should not be embarked on lightly.

Clinical Caveats

Symmetry of the mound and nipple position must be created.

Abnormally placed breast creases should be eradicated and re-created at a natural level.

Radial scoring is performed perpendicular to the crease to eliminate a tight crease.

Broad-based pedicles are raised in revisionary surgery.

A herniated areola can be reduced by performing a periareolar mastopexy.

Annotated Bibliography

Baroudi R, Lewis JR. The augmentation-reduction mammoplasty. *Clin Plast Surg* 3:301-308, 1976.

The authors present a technique of augmentation mammoplasty with simultaneous treatment of glandular ptosis for patients with small, ptotic breasts. The technique has several advantages: it is simple and poses no circulatory problems to the flaps, the hospital stay and recovery are short, and only one procedure is required.

Gliosci A, Presutti F. Asymmetry of the breast: some uncommon cases. *Aesthetic Plast Surg* 18:399-403, 1994.

Six cases of significant asymmetry are presented. Treatment involved elaborate corrective methods.

Hammond DC. Surgical correction of gynecomastia. *Plast Reconstr Surg* 124(1 Suppl):61e-68e, 2009.

The author describes two types of tissue in patients with gynecomastia as well as treatment modalities.

Spear SL, Davison SP. Aesthetic subunits of the breast. *Plast Reconstr Surg* 112:440-447, 2003.

A subunit principle for breast reconstruction is presented based on a review of 10 years of autogenous reconstruction. Patterns of breast subunits are identified for defects of various sizes.

Vandenbussche F. Asymmetries of the breast: a classification system. *Aesthetic Plast Surg* 8:27-36, 1984.

The author proposes four main categories of breast asymmetry based on a review of 150 cases. These groups are true malformative asymmetry of breast, precocious primary asymmetry of breast, secondary or progressive acquired breast asymmetry, and tertiary or induced breast asymmetry.

CHAPTER 74

Treatment of Gynecomastia

DAX GUENTHER, RICHARD Y. HA,
ROD J. ROHRICH, JEFFREY M. KENKEL

Gynecomastia is a condition in which unilateral or bilateral benign excessive breast development occurs in males. This is often an embarrassing and psychologically troubling problem that prompts the patient to seek correction. Initially thought to be a rare condition, a Navy study of recruits during World War II reported an incidence of 25% with excess breast tissue; more recent studies have reported an overall incidence of 32% to 36%, even as high as 40% of men in an autopsy series, and 64.6% in adolescent boys. The incidence of bilateral involvement also varies in the literature. The condition occurs bilaterally in 25% to 75% of patients. This wide variation probably stems from an increased appreciation of the psychological, physical, and social impact of the condition, as well as the lack of a clear and standardized definition within the plastic surgery and medical literature.

Etiologic Factors

The cause of gynecomastia is multifactorial, but in many cases an identifiable cause is elusive. Most authorities attribute the condition to stimulation of breast tissue by excess circulating estrogens or estrogen-like substances; this has been the basis for recent attempts at medical therapy for gynecomastia. However, surgical removal of the hypertrophic breast tissue remains the standard of treatment.

Gynecomastia has many identifiable causes, although idiopathic causes are the most common (25%). Recent investigations have demonstrated pathophysiologic mechanisms that involve a relative or absolute excess of estrogens, a decrease in circulating androgens, or a defect in androgen receptors. There is strong evidence for the estrogen-stimulating effects of breast tissue development as well as support for an inhibitory androgenic effect. Decreases in the androgen-to-estrogen ratio have also been associated with development of gynecomastia. No clear etiologic classification has been suggested based solely on hormonal influences. Instead, most accept an arbitrary classification based on physiologic, pathologic, pharmacologic, and idiopathic causes.

Physiologic gynecomastia can be further subdivided into neonatal, pubertal, and elderly periods. Circulating maternal estrogens transferred by the placental-fetal circulation are thought to contribute to excessive development of breast tissue in neonates. Because this is usually a self-limiting process lasting from weeks to months, treatment is rarely indicated. Up to 65% of adolescent boys exhibit varying degrees of gynecomastia, which usually resolves over several months to years. The degree of breast enlargement can be so minor as to escape recognition unless the area is clinically palpated. Relative excess of plasma estradiol compared with testosterone is implicated in the pathogenesis of pubertal gynecomastia. Older men (beginning at age 65) will often develop breast enlargement as plasma testosterone levels decline and peripheral conversion of testosterone to estrogen (peripheral aromatization) occurs, thus effectively increasing the plasma estrogen-to-androgen ratio.

Causes of Gynecomastia

Developmental/Physiologic

Neonatal
Pubertal
Aging

Drug-Induced (see box on p. 2650)

Hypogonadism

(decreased androgen synthesis or increased androgen resistance)

Primary
Acquired (trauma, infection, torsion, radiation exposure, mumps, chemotherapy)
Congenital
Secondary
Hypogonadotropic hypogonadism
Kallmann's syndrome
Pituitary failure (infarction, infection, neoplasm)

Tumors (increased estrogen production)

Steroid-producing (adrenal, testis)
HCG-producing (testis and others)
Aromatase-producing (testis)
Bronchogenic carcinoma

Systemic

Thyrotoxicosis (altered testosterone/estrogen binding)
Renal failure (acquired testicular failure)
Cirrhosis (increased substrate for peripheral aromatization)
Adrenal (ACTH deficiency or congenital adrenal hyperplasia)

Congenital Disorders

Klinefelter's syndrome
Enzyme defects of testosterone synthesis (may be late onset)
Vanishing testis syndrome (anorchia)
Androgen resistance syndromes
True hermaphroditism and related conditions
Increased peripheral tissue aromatase

Familial

HIV
Chest wall trauma
Psychological stress
Spinal cord injury
Malnutrition/refeeding (increased substrate for peripheral aromatization)
Herpes zoster infection
Cystic fibrosis
Alcoholism
Myotonic dystrophy

Idiopathic

ACTH, Adrenocorticotrophic hormone; HCG, human chorionic gonadotropin; HIV, human immunodeficiency virus.

Pathologic gynecomastia occurs as a result of various metabolic disorders (alcoholic cirrhosis, refeeding after a starvation state, feminizing adrenal tumors), endocrine disorders (hyperthyroidism, adrenal cortical hyperplasia, hypothyroidism), acquired hypogonadal states (orchitis, testicular trauma, granulomatous disease, renal failure, alcoholism, myotonic dystrophy), congenital hypogonadal states (Klinefelter's syndrome, congenital anorchia, androgen resistance), and increased estrogen states (bronchogenic carcinoma, true hermaphrodisism, testicular tumors).

Drug-Induced Gynecomastia

I. Drug Classes Associated With Gynecomastia

- Estrogens
- Gonadotropins
- Androgens (aromatizable)
- Antiandrogens (cyproterone, flutamide)
- Cancer chemotherapy agents (especially alkylating agents)
- Calcium channel blockers (verapamil, nifedipine, diltiazem)
- ACE inhibitors (captopril, enalapril)
- Antihypertensives (methyldopa, reserpine)
- Digitalis preparations
- Dopamine blockers (phenothiazines, metoclopramide, domperidone)
- Central nervous system agents (tricyclics, diazepam, phenytoin, diethylpropion)
- Drugs of abuse (marijuana, heroin, methadone, amphetamines)
- Antituberculous agents (isoniazid, ethionamide, thiacetazone)

II. Individual Drugs Commonly Associated With Gynecomastia

- Cimetidine
- Spirolactone
- Ketoconazole

III. Miscellaneous Drugs Related to Gynecomastia

- Amiodarone
- Auranofin
- Clomiphene
- Etretinate
- Metronidazole
- Omeprazole
- Penicillamine
- Sulindac
- Theophylline

ACE, Angiotensin-converting enzyme.

Pharmacologic gynecomastia can occur by several mechanisms, such as increased direct estrogenic activity, increased secretion of estrogen, decreased testosterone synthesis, and decreased androgen sensitivity. Also, many drugs with poorly understood mechanisms of action are associated with gynecomastia.

Bannayan and Hajdu identified three histologic patterns with varying degrees of stromal and ductal proliferation: florid, intermediate, and fibrous types. The florid pattern shows increased numbers of budding ducts in a highly cellular fibroblastic stroma. The fibrous type has extensive stromal fibrosis with minimal ductal proliferation. The intermediate type demonstrates overlapping of the fibrous and florid histologic patterns. Most experts agree that these patterns represent a transition related to the duration of gynecomastia and its symptoms, with the florid type usually seen in gynecomastia of less than 4 months' duration and the fibrous type seen when the gynecomastia has persisted for more than 1 year.

Associated Risks of Male Breast Cancer

One percent of all breast cancer occurs in males. However, patients with Klinefelter's syndrome have up to a 60 times greater risk of developing breast cancer; the incidence is approximately 1 in 400 to 1 in 1000. Many studies reviewing males with gynecomastia have demonstrated no increased risk of breast cancer compared with the normal male population. Thus in all non-Klinefelter's patients it is reasonable to treat gynecomastia surgically with both liposuction and excisional techniques without adding considerable morbidity or delaying the detection of male breast cancer.

In patients in whom hypogonadism is suspected, Klinefelter's syndrome must be ruled out, because this will ultimately have an impact on treatment. Because of the oncologic risk, excisional techniques are preferred for these patients.

Evolution of Treatment

Gynecomastia of long duration is unlikely to regress spontaneously and will often progress to irreversible dense fibrosis and hyalinization despite medical therapy. Withdrawal of an offending drug, correction of a systemic disorder, or the natural course of physiologic gynecomastia often results in spontaneous regression of gynecomastia; however, correction of an underlying disorder may not be effective in treating gynecomastia, especially if the duration of disease is lengthy and fibrosis of breast tissue has already occurred. Thus surgery remains the standard for management.

Evolution of Surgical Techniques for Gynecomastia

Year	Innovator(s)	Surgical Technique
1946	Webster	Semicircular intraareolar incision (resection of cone-shaped mass of breast tissue centrally with peripheral taper; reapproximate fat beneath areola)
1964	Barsky and Simon	Inverted omega intraareolar incision (improved exposure to under surface of areola)
1966	Pitanguy	Horizontal transareolar/intraareolar incision (improved exposure, easier dissection, and hemostasis)
1969	Letterman and Schurter	Superior periareolar incision with skin excision (for moderate to large gynecomastia; excess skin resected and nipple transposed superiorly)
1972	Letterman and Schurter	Nipple transposition on single dermal pedicle with oblique incision (nipple transposed medially and superiorly)
1972	Pers	Nipple transposition on vertical bipedicle with horizontal incision
1973	Simon	Excision redundant skin/breast tissue with free nipple graft (excision located as ellipse around nipple)
1974	Eade	Radial intraareolar incision
1974	Wray	Excision redundant skin/breast tissue, nipple grafting with inframammary fold scar (en bloc excision of breast tissue/skin with free nipple grafting; inframammary fold scar not in continuity with new nipple position)
1978	Balch	Transaxillary approach (2-inch incision in axilla)
1978	Artz and Lehman	Dermal pedicle
1979	Davidson	Concentric circle technique (half-circle serves as dermal pedicle; remaining half resected with breast tissue)
1981	Fara	Single superior dermal pedicle
1982	Huang	Concentric circle technique modification (no dermal pedicle; "apple core" around nipple/areola, vascular supply from chest wall)
1983	Teimourian and Perlman	SAL with excision (SAL used in periphery to smooth contour)
1986	Mladick	SAL
1987	Rosenberg	SAL (SAL used to evacuate both adipose tissue and dense parenchymal tissue in the breast, citing use of smaller 2.4 mm cannula as critical component for effective evacuation of the dense parenchyma)
1987	Courtiss	SAL (useful in selected patients with predominantly fatty breasts and well-located nipple/areola)
1994	Samdal	SAL
1994	Abramo	SAL (axillary approach for suction lipectomy)
1998	Smoot	Eccentric skin resection and purse-string closure
1998	Ohyama	Endoscopic transaxillary approach
1998	Botta	Circumareolar skin and SAL (technique described for patients with severe gynecomastia)
1998	Rohrich, Beran, and Kenkel	UAL (UAL technique reviewed, used successfully in all three grades of gynecomastia)
1999	Chiu	Pinwheel technique
1999	Gingrass	UAL (excellent results using UAL for most types of gynecomastia)

Surgical management, until recently, mostly consisted of excisional techniques. Standard suction-assisted lipoplasty (SAL) had an adjunctive role and was also advocated as a primary mode of treatment. However, limitations were encountered when SAL was used to treat severe cases or in breasts composed of primarily fibrous tissues.

Ultrasound-assisted liposuction (UAL), with known mechanical advantages in addressing dense, fibrous lipodystrophy, has extended the role of lipoplasty in the management of gynecomastia and has emerged as the preferred treatment modality. The technique was first described with the use of ultrasonic energy transmitted through excited piezoelectric crystals placed on terminal ends of suction cannulas to emulsify fat while preserving adjacent nervous, vascular, and connective tissue elements. Emulsification is effected through cavitation of fat cells in tumesced fields.

The UAL technique has been further refined, incorporating a three-stage process of subcutaneous infiltration of a wetting solution, followed by UAL, and completed by evacuation and final contouring by SAL. Endpoints for UAL (time and loss of resistance) differ from those for standard SAL (pinch and contour) but now provide parameters for safe and efficient lipectomy. Power-assisted liposuction (PAL) has provided a useful modality for treating patients with more fibrous gynecomastia. There have also been reports of laser lipolysis with pulsed 1064 nm Nd:YAG laser for the treatment of gynecomastia. Regardless of the technology used, an aggressive surgical approach is required to treat the more fibrous type of gynecomastia.

Advantages of Ultrasound-Assisted Liposuction

UAL has several advantages over SAL in the treatment of gynecomastia. Several studies have confirmed the selective emulsification of fat, which leaves higher-density structures such as fibroconnective tissue relatively undamaged. This allows more efficient removal of fat in areas that have higher densities of fibroconnective tissue, such as the male breast. At higher energy settings, UAL is effective in removing the denser fibrotic parenchymal tissue that SAL is inefficient in removing. In addition, UAL performed in the appropriate subdermal plane affects the dermis, aiding in skin retraction in the postoperative healing period. Further advantages of UAL include the reduced physical demand for large-volume liposuction of the breast, which allows the surgeon to contour the chest more precisely.

Indications and Contraindications

Some patients respond to nonsurgical management to correct underlying causes; these treatments include medications to regulate hormonal imbalances and irradiation. However, medical therapy with testosterone, antiestrogens (clomiphene and tamoxifen), and danazol has met with only limited success.

The surgeon and patient should consider proceeding with surgical management once a diagnosis of gynecomastia from nonphysiologic causes is established or if gynecomastia persists for longer than approximately 12 months. Hypertrophic breast tissue beyond this stage usually becomes irreversibly fibrotic. Patients with Klinefelter's syndrome should be treated by mastectomy because of the increased risk of malignancy. An algorithm for the diagnosis and directed treatment of gynecomastia is suggested (see p. 2660).

Pertinent Anatomy

In a normal male, the breast is typically flat, with some fullness around the nipple-areola complex. Glandular tissue is limited to the area directly beneath the nipple and areola and is usually not palpable as a discrete mass. A muscular male chest may exhibit superior fullness with a transition to a flat inferior chest near the inframammary fold. The nipple-areola complex is normally 2 to 4 cm in diameter and located over the fourth intercostal space. Nipple-to-sternal notch distance is 20 cm on average. Swelling associated with gynecomastia may occur as a circumscribed, firm, glandular mass of varying size just beneath the areola, or it may be a diffuse fatty fullness of the chest with ill-defined margins. Extensive glandular enlargement extending well beyond the areola has been described in body builders who use anabolic steroids.

Preoperative Assessment

A thorough medical history and clinical evaluation of the patient with gynecomastia are paramount. However, further workup is rarely indicated. The history elicited should include age, duration and onset of breast enlargement, symptoms of pain or tenderness, medications and recreational drug use, and psychological and social effects. A review of systems should involve signs and symptoms of hepatic disease, hyperthyroidism or hypothyroidism, recent weight gain or loss, adrenal disease, alcoholism, renal failure, and malignancies.

Physical examination of the breasts should involve assessment for glandular or fat predominance (by the pinch test), degree of glandular ptosis, skin excess, nodules or masses, and nipple abnormalities or discharge. Glandular or parenchymal tissue is characterized by rubbery breast tissue that is mobile and extends from a subareolar centric position. Suspicious nodules or masses may have abnormal firmness, overlying skin ulceration, eccentric location, or abnormal nipple discharge. In addition, the physical examination should look for testicular enlargement or atrophy and asymmetry, thyromegaly, hepatomegaly, pulmonary abnormalities, and abdominal masses.

Additional diagnostic testing should be individualized to address abnormalities identified in the history or physical examination. Cohen et al and McGrath suggested individualized workups, depending on the patient's age at the time the gynecomastia developed. These considerations are important, but arbitrary use of "screening" tests or laboratory data is not recommended. Rarely is an extensive workup indicated, and often this will have no impact on treatment.

Guidelines for Clinical Evaluation of Gynecomastia

	Consider	Tests
Prepubertal girls	Premature thelarche Exogenous hormones or drug usage Premature puberty Feminizing adrenal carcinoma	Serum estradiol level CT scan abdomen/adrenal LH/FSH (elevations may occur only at night) Bone age
Prepubertal boys	Idiopathic cause Drug use Premature puberty Feminizing carcinoma (Leydig cell tumor, adrenal carcinoma)	Serum estradiol LH/FSH HCG Bone age If HCG elevated, testicular ultrasound or thermography $\pm$ karyotype
Pubertal males with normal external genitals	Physiologic Klinefelter's syndrome Congenital anorchism Drug use Feminizing carcinoma (Leydig cell tumor, adrenal carcinoma)	LH/FSH Testosterone (total and free) Estradiol HCG If testosterone low and LH/FSH elevated, karyotype If estradiol is elevated, adrenal CT scan
Pubertal males with ambiguous genitals	Androgen biosynthetic defects Partial androgen resistance True hermaphrodism Mixed gonadal dysgenesis	LH/FSH Testosterone (total and free) Estradiol Karyotype Scans or exploration as indicated $\pm$ Androgen receptor analysis $\pm$ Androgen biosynthetic intermediate
Adult males	Testicular failure (viral orchitis, trauma) Ectopic gonadotropin production Feminizing adrenal carcinoma Drug use Chronic liver disease/cirrhosis Renal failure Thyrototoxicosis Idiopathic causes	LH/FSH Testosterone Estradiol HCG

FSH, Follicle-stimulating hormone; HCG, human chorionic gonadotropin; LH, luteinizing hormone.

Certain clinical findings should prompt further evaluation. In the scenario of a young (especially prepubertal) patient with a normal history and bilateral gynecomastia, testicular ultrasonography in conjunction with a careful testicular examination has been found to be cost-effective. The incidence of a functional endocrine tumor in this group is significant. Physical examination findings of feminization, including small testicular size (less than 3 cm in length or 8 cc in volume), lack of male hair distribution, or a eunuchoid body habitus, suggest a possible feminizing tumor. Endocrine testing in this situation (serum testosterone, luteinizing hormone, estradiol, and de-

hydroepiandrosterone) is appropriate. If feminizing characteristics are found in association with a marfanoid body habitus, karyotyping and an endocrine referral are indicated to rule out Klinefelter's syndrome.

Preoperative Planning

Classification and Treatment

Several treatment classification systems have been developed and excellent guidelines have been proposed for graduated management of gynecomastia based on degrees of lipodystrophy and skin excess.

We proposed a classification system in which candidates for surgical treatment are graded on the basis of the amount and character of breast hypertrophy, as well as the degree of ptosis. These grades can be further subdivided into grades IA and IIA for primarily fatty breast tissue and grades IB and IIB for primarily fibrous breast tissue. In this system, UAL and SAL are the primary treatment modalities.

Classification and Management of Gynecomastia	
Grade I	Minimal hypertrophy (<250 g of breast tissue) without ptosis
IA	Tissue type: Primarily glandular* Treatment: UAL or SAL
IB	Tissue type: Primarily fibrous* Treatment: UAL or SAL
Grade II	Moderate hypertrophy (250-500 g of breast tissue) without ptosis
IIA	Tissue type: Primarily glandular* Treatment: UAL or SAL
IIB	Tissue type: Primarily fibrous* Treatment: UAL or SAL
Grade III	Severe hypertrophy (>500 g of breast tissue) with grade I ptosis
	Tissue type: Glandular or fibrous* Treatment: UAL, 6-month staged excision†
Grade IV	Severe hypertrophy (>500 g of breast tissue) with grade II or III ptosis
	Tissue type: Glandular or fibrous* Treatment: UAL, 6-month staged excision†

*Fatty and glandular tissue is determined by a pinch test medially, laterally, and beneath the nipple-areolar complex.

†Delayed excision of remaining ptotic breast skin and/or breast parenchyma is performed 6 to 9 months after UAL to allow for maximal skin retraction.

Grade I

Patients with grade I gynecomastia have minimal hypertrophy (less than 250 g of breast tissue).

Grade II

Patients with grade II gynecomastia have moderate hypertrophy (between 250 and 500 g of breast tissue).

Grades III and IV

Patients with grades III and IV gynecomastia have severe hypertrophy (greater than 500 g of breast tissue) but are distinct because they have a greater degree of ptosis. Patients with grade III gynecomastia exhibit grade I ptosis, whereas patients with grade IV gynecomastia have grade II or III ptosis.

Power-assisted liposuction (PAL) and UAL are effective in all grades of gynecomastia. While they remain the primary treatment modality, increasingly it is becoming common to supplement PAL or UAL with partial resection of the retroareolar fibroglandular tissue. This may be accomplished via minimal periareolar incisions or the incisions used for the liposuction. Usually no further treatment is needed in grade I or II gynecomastia, and often a single UAL or PAL treatment is all that is necessary for grades III and IV, especially in patients with mild ptosis and good skin quality. Suction-assisted liposuction is a suboptimal modality for more severe gynecomastia (grades III and IV) and for patients whose glandular component is primarily fibrous tissue. Patients with grades III and IV gynecomastia may require staged excision.

EVALUATION AND TREATMENT OF GYNECOMASTIA

CT, Computed tomography; DHEAS, dehydroepiandrosterone; FSH, follicle-stimulating hormone; LH, luteinizing hormone.

Operative Technique

Markings

Markings are made preoperatively to outline boundaries of treatment. The outer perimeter of the breast base is marked initially, followed by the area of breast enlargement. The inframammary fold should be marked preoperatively with the patient sitting or standing. Adherent zones in the upper outer quadrants, where the breast retreats into axillary tissue, should be suctioned with caution.

Incision Placement

UAL access incisions are made inferolaterally in the inframammary fold. Occasionally, a second incision is made near the anterior axillary fold to facilitate evacuation and final contouring in patients with grade III ptosis and large fat deposits. UAL should not be performed through this incision because the overlying skin is quite thin and prone to thermal injury.

Anesthesia

A general anesthetic is administered, and the patient is positioned supine with the arms abducted. Incisions (3 to 4 mm) are made with a No. 11 scalpel in the lateral inframammary folds bilaterally for optimal access to the dense breast parenchyma. This route also provides superior access to obliterate the inframammary fold and to suction the medial chest.

Subcutaneous infiltration of wetting solution in the intermediate fat layer is performed using a standard infiltration pump and a 3 mm cannula. A superwet technique with a 1:1 ratio of infiltrate to estimated aspirate is used with a solution containing 1 L of lactated Ringer's solution mixed with 1 ampule of 1:1000 epinephrine and 30 cc of 1% lidocaine. Uniform infiltration can be challenging, and it is important to infiltrate all treatment areas in multiple layers systematically.

Technique

UAL is performed with an ultrasound generator (Mentor, Santa Barbara, CA, or LySonix, Carpinteria, CA), a 5 mm blunt-tipped titanium cannula or a 4 mm golf-tee cannula, and a standard surgical aspirator for evacuation. The Mentor Contour Genesis generator is set at an energy level ranging from 70% to 90%, with 90% being especially effective in the denser subareolar areas. The energy level on LySonix generators should be set between 5 and 7.

Volumes of aspirate and time of application are recorded. If the Vaser system is used (see Chapter 78), a single ring probe in the continuous mode at higher energy levels (greater than 90%) is effective. The stroke technique involves constant, deliberate passes of the cannula through the intermediate fat layer in a radial fashion from the lateral inframammary fold incisions. Additional passes are concentrated in the unique subareolar region where maximal fibroconnective density occurs.

A bimanual technique is used, with the nondominant hand guiding the UAL cannula through the subdermal layer. Liposuction of the subdermal layer is not a traditional level of treatment in UAL, but it is particularly important in addressing the dense fibrous tissue of gynecomastia and allowing maximal skin retraction. The periphery is treated for feathering and contouring. Disruption of the inframammary fold is essential in achieving a more gradual transition of the breast to the abdomen, which is characteristic in males (as opposed to the distinct demarcation of the inframammary fold in females). The adherent zones in the upper outer quadrants, as the breast retreats into axillary tissue, should be suctioned minimally, if at all (only for contouring), and extreme caution should be exercised.

PAL is also effective in treating gynecomastia. It is excellent for initial fat removal in fibrous areas, followed by treatment with SAL.

SAL is performed in standard fashion using 3.0 and 3.7 mm cannulas for final contouring and evacuation of emulsified fat. Evacuation should occur from the deep fat layer to the intermediate fat layer. Great care is taken to avoid overcontouring the area overlying the upper lateral pectoralis major muscle. After evacuation is complete, incisions are closed with 5-0 fast-absorbing plain gut sutures.

It is important to remember that the goal of UAL, PAL, or SAL in the treatment of gynecomastia is to restore normal male breast contour, not to eliminate all breast tissue. Achieving optimal results involves eliminating the excess breast tissue and performing peripheral contouring. The normal male breast has some subareolar fullness,

with varying degrees of superior chest wall volume. Using UAL, PAL, or SAL appropriately can avoid the “saucer deformities” that can be seen with overzealous resection from excisional techniques.

If additional contouring is necessary, an inferior semicircular periareolar incision is made to allow for direct access to any remaining fibroglandular tissue. Fibrous fragments are sequentially grabbed with a clamp and sharply excised under direct vision. Care is taken to not overly thin the subareolar area as this will create a contour depression. Leaving an approximately 0.5 cm thick portion of retroareolar glandular tissue avoids this complication.

Our preference is not to address skin excess at the initial operation. If removal of redundant skin and/or resistant lipodystrophy is still required after UAL or PAL, a staged excision is delayed for 6 to 9 months to allow for maximal skin retraction and healing. Thus the magnitude of the excisional technique and the resultant scarring can be minimized. A staged excision can be accomplished through a periareolar approach in most cases. Excision through extensive breast mound incisions has rarely been required.

Postoperative Care

The chest wall is dressed with a double layer of TopiFoam, and the patient wears a compressive vest for 4 weeks, 24 hours a day, followed by 4 weeks at nighttime only. Compressive therapy is critical in the postoperative period to prevent seroma or hematoma formation and to provide optimal contouring.

Patients should be followed periodically. Transient alterations in nipple sensation are rare, and affected patients can be reassured that sensation will return. If redundant skin or fibrous tissue persists, staged excision can be accomplished 6 to 9 months after surgery.

Outcomes

Courtiss reviewed 159 patients who underwent surgical management for gynecomastia; 101 patients (192 breasts) were treated with excisional techniques. Courtiss reported a high rate of complications with excisional techniques, including overresection (18.7%), unattractive scarring (18.7%), hematoma (16.1%), seroma (9.4%), and underresection (21.9%).

In a series of 60 patients treated with UAL reported by Gingrass, no major complications, hematomas, or episodes of skin necrosis were reported over a 4-year follow-up period; results were reported as “uniformly good to excellent.”

In a review of 61 patients by Rohrich and colleagues, no additional treatment was required in 86.9% of patients (53/61). Eight patients, four with grade III disease and four with grade IV gynecomastia, required staged excision of remaining breast tissue and skin (6 to 9 months after UAL) to optimize results.

Results

The following patients were treated with a combination of SAL and UAL for gynecomastia grades I through IV. All postoperative results demonstrate excellent restoration of normal male breast contour.

This 32-year-old man with grade IA gynecomastia was treated by UAL; 175 cc was removed from each side. He is seen 6 months postoperatively.

This 13-year-old boy with grade III gynecomastia was treated with UAL of the chest and disruption of the inframammary fold; approximately 350 cc was removed from each side. His initial result is seen 1 year later. He requested further improvement, so a second procedure was performed (*bottom row*) in which a persistent glandular remnant was removed and a periareolar skin excision was performed.

This 22-year-old man had grade IA gynecomastia. He underwent UAL removal of 200 cc from each side. He is seen 15 months postoperatively.

This 19-year-old man had grade IIB gynecomastia. He underwent UAL removal of 375 cc from each side. He is seen 6 months postoperatively.

This 26-year-old man presented with grade IA gynecomastia. He is seen 6 months postoperatively after UAL removal of 200 cc from both sides of the chest and disruption of the inframammary fold.

This 16-year-old boy presented with grade IIA gynecomastia. He underwent evacuation of approximately 300 cc from both sides of the chest. He is seen 1 year post-operatively with a significantly improved contour.

This 36-year-old man had grade IIB gynecomastia. UAL and SAL procedures removed 725 cc from his left side and 700 cc from his right side. He is seen 8 months postoperatively with good symmetry and skin retraction.

This 38-year-old man presented with grade III gynecomastia. He is shown 7 months postoperatively after removal of 650 cc from the right side and 600 cc from the left.

This 18-year-old was diagnosed with grade IV gynecomastia; he subsequently underwent evacuation of 750 cc on the right side and 700 cc on the left side. Although there is some persistent ptosis postoperatively, he shows marked improvement for this more severe form of the disease.

Concluding Thoughts

The treatment of gynecomastia continues to be challenging because of the dense nature of the breast tissue as well as the skin redundancy that is often present. We have no doubt that some of the nonsurgical devices under investigation will be included in treatment algorithms of the future.

Clinical Caveats

Gynecomastia that is present clinically for more than 12 months does not typically resolve completely.

The goal of treatment is restoration of a normal male breast contour, not elimination of all breast tissue.

Excision alone should be avoided as the primary treatment for gynecomastia.

The lateral inframammary fold incision is optimal to concentrate UAL/SAL or PAL/SAL passes in the dense subareolar region.

Liposuction should be performed cautiously in the adherent zone.

UAL and PAL are effective for all grades of gynecomastia; SAL is primarily effective for grades IA and IIA.

Annotated Bibliography

Courtiss EH. Gynecomastia: analysis of 159 patients and current recommendations for treatment. *Plast Reconstr Surg* 79:740-750, 1987.

The author presents the following treatment recommendations for gynecomastia: if the gynecomastia is entirely due to fat, suction lipectomy alone is sufficient treatment. However, because suction will not remove breast parenchyma, patients whose gynecomastia is caused by parenchymal hypertrophy also require local excision of the parenchyma. Skin excision is rarely, if ever, necessary.

PART XII

BODY CONTOURING

CHAPTER 75

Applied Anatomy in Body Contouring

ANGELA S. LANDFAIR, J. PETER RUBIN

Appplied anatomy is the practical application of anatomic knowledge to diagnosis and treatment of a patient. Applied anatomy in body contouring demands more than a passing familiarity with the underlying muscular, neurovascular, and bony structures. During body-contouring surgery, substantial three-dimensional zones of tissues may be simultaneously manipulated, transferred, and transformed. Therefore intimate knowledge of the subcutaneous tissue structure and composition and its relationship to the deeper tissues below is essential in optimizing surgical outcomes.

In this chapter we will review relevant universal anatomic principles that affect body contouring, with an emphasis on the superficial fascial system (SFS), zones of adherence, and the lymphatic system. Comprehension of these anatomic systems can help surgeons refine their technique and ultimately improve outcomes. Our discussion is not meant to describe operative techniques that are more extensively and appropriately discussed elsewhere; we will focus on the application of broad anatomic concepts for various surgical zones in body contouring.

Evolution of Technique

In the past four decades, the science of body contouring has reached new levels of sophistication and ingenuity. In the 1970s there were tremendous advances in suction-assisted lipectomy, followed by innovations in tumescent, ultrasound-assisted, and large-volume liposuction. The surgeon's abdominoplasty repertoire has been augmented by the mini-abdominoplasty, marriage abdominoplasty (combination of mini-abdominoplasty and liposuction), limited dissection abdominoplasty, and lipoabdominoplasty, among others. Lockwood's descriptions of the superficial fascial system provided an anatomic basis for highly transformative excisional body-lifting procedures. Circumferential body contouring began with belt lipectomy and now encompasses various excisional lifting procedures, including simultaneous circumferential upper and lower body lifts.

The most recent advances in body contouring can be attributed to the increasing demand for bariatric surgery. Massive-weight-loss patients have presented many new challenges to plastic surgeons, introducing many unfamiliar contour deformities that had been inadequately addressed by previously existing procedures.

Ever the innovators, plastic surgeons have devised new procedures to address the deformities associated with massive weight loss. As our surgical arsenal grows in breadth and complexity, we can benefit by reevaluating the anatomic tenets that define the limits of tissue dissection and resuspension.

Superficial Fascial System

The superficial fascial system (SFS) is a vast connective tissue network extending from the dermis to the muscular fascia. The SFS comprises vertically and horizontally oriented fibers that interconnect to form a *connective tissue scaffold*. The vertical SFS fibrils arise directly from the deep dermis and attach to one of three locations: another SFS fibril; a secondary SFS layer, such as Scarpa's fascia; or directly to the muscular fascia. The SFS provides structure and a strut for subcutaneous fat and imparts additional biomechanical strength to surgical closures. Pathologically, the SFS is responsible for dimpling and cellulite. Manipulation of SFS has been discussed as a critical step in both excisional and less-invasive body contouring.

Histologically, the collagen and elastin content of the SFS is indistinct from that of the deep dermis. In the deep reticular dermis, the collagen and elastin fibers that are mostly horizontal in mid-dermis begin to orient themselves obliquely at angles that are more perpendicular to the epidermis. At the dermis-SFS junction, there are connective tissue fibers that emerge in a nearly vertical direction. The vertical SFS fibrils transmit interconnecting, more horizontal fibers to adjacent fibrils.

The SFS has a secondary component: the thin, gossamer sheets that emerge from the fibrils to encase the fat globules interspersed among the scaffold. These fine connective tissue sheets suspend the adipose tissue in their three-dimensional position.

The collagen and elastin makeup of the SFS fibrils indicates that the SFS shares viscoelastic properties similar to those of the dermis, including creep (lengthening of tissue under tension) and stress relaxation (decreased inherent tissue tension when pulled bidirectionally over time). In biomechanical testing of subcutaneous tissues, the SFS layer demonstrates viscoelastic properties independent of those of the dermis. When repaired along with dermis, the SFS confers supplementary initial tensile strength to wound repair.

In our animal study, suture approximation in the SFS layer, in addition to the dermis, significantly increased the initial biomechanical strength of the surgical repair and probably had a role in increasing permanent wound strength. Anchoring the SFS to deep fascia during closure has also been credited with decreased migration and widening of surgical scars.

In limited areas of the body, the SFS has a distinct, substantial horizontal layer that is suspended between the dermis and the muscular fascia below. This layer is called *Scarpa's fascia* in the trunk and *Colles' fascia* in the perineum. These defined connective tissue scaffolds most likely provide the majority of the tensile strength of the SFS layer when incorporated in body contouring. In other areas such as the lower legs, the SFS consists of layers of vertical fibrils and connecting horizontal fibers that do not coalesce into a substantial intervening horizontal structure.

Sex differences in SFS have yet to be satisfactorily elucidated. In general, however, the vertical components of the SFS are oriented more perpendicularly in women and more obliquely, or in a crisscross pattern, in men. As previously mentioned, the SFS scaffold consists of predominantly vertical/vertical-oblique fibers, with horizontal connecting fibers. It has been observed that in women with cellulite, there is a paucity of the horizontal fibers compared with women without cellulite, and that women without cellulite have SFS anatomy more similar to that of men.

The appearance of dimpling after overaggressive liposuction is probably caused by hollowed-out SFS pulling on the dermis. The appearance worsens with movement: the unidirectional pull of the SFS fibers emphasizes the dimples. The sex differences have not been investigated in morbidly obese or postbariatric patients. A reasonable assumption is that the overall effacement of SFS fibers and decreased elastin content seen with massive weight loss is likely to have a greater impact on SFS architecture than the sex of the patient does.

SFS is a dynamic viscoelastic structure that relaxes with age and weight gain. Stretching of these organized SFS fibrils is probably partially responsible for pathologic dimpling of the skin (cellulite) and for horizontal descent of tissues above more densely adherent areas, as seen in ptosis of the mons pubis. The impressive skin and soft tissue rolls often seen in massive-weight-loss patients arise from stretching and relaxation of skin and SFS, with deflation of the adipose tissue from weight loss. In areas of excess adiposity, SFS stretches from the burden of the intervening adipose tissue, and it is often difficult to distinguish distinct SFS fibers in areas of excess adiposity. In massive-weight-loss patients, the SFS fibers have been stretched to conform to a much larger tissue burden and often appear effaced in areas of greatest adipose loss.

To equate body contouring with construction, the superficial fascial system is the scaffold. The SFS exists in every area of body contouring, and a successful outcome depends in large part on SFS reshaping and resuspension. Even when effaced by obesity and subsequent massive weight loss, the SFS remains an important layer in restructuring subcutaneous fat and minimizing scar and tissue migration.

Zones of Adherence

The topographic anatomy of the body is determined by the relationship of the SFS to the dermis above and the muscular fascia below. An area in which the SFS is specifically adherent and thickened creates a linear crease in the skin and a valley in the immediately surrounding soft tissue. These zones of adherence divide the adjacent subcutaneous tissue on either side into surgical compartments.

The zones of adherence have been emphasized in the past because they were considered zones to be avoided during suction lipectomy. Avoiding suctioning across these zones would result in conservation of subcutaneous connections between the skin and muscle fascia, thus preventing the overlying skin from vertical descent.

However, the classic zones of adherence are often not zones of avoidance in the massive-weight-loss population. In excisional lifting procedures, tissues within the zones of adherence may be excessive and should undergo direct resection. In the most severe massive-weight-loss deformities, the inferior tissue flaps may need to be draped over and superior to the existing zone of adherence and anchored at a more superior location. The new site to which the tissues are anchored may act as a *de novo* zone of adherence.

The zones of adherence do not occur equally between the sexes. The hip zone of adherence is demonstrated most convincingly at the level of the iliac crest in men, but several centimeters below the iliac crest in women. Adiposity below this zone of adherence in women accentuates the so-called saddlebag deformity, a finding largely absent even in obese men.

In massive-weight-loss patients, the combination of excess skin and attenuated SFS fibers creates large hanging areas that can originate and/or terminate at the various zones of adherence. An example of this is a moderate-sized pannus protruding and then descending over a known zone of adherence in the suprapubic zone, with the inferior margin of the pannus coalescing and attaching to the same zone of adherence. In female massive-weight-loss patients, significant deflation and ptosis of the breast occurs, with the majority of the ptotic tissue descending and hanging below the inframammary fold, which is an important zone of adherence. This phenomenon is seen in men as well, although to a lesser degree.

Pathologic zones of adherence are often observed in massive-weight-loss patients. For instance, the lateral chest roll that is often seen as a continuation of the breast suggests that the fascial coalescence that defines the inframammary fold continues laterally, causing overhang of lateral chest wall tissue in continuity with the breast tissue. The pathologic inframammary fold continuation into the lateral chest wall is likely present to some degree in all patients; however, this attachment is probably clinically insignificant in the nonobese and never-obese population, who do not have a significant quantity of lateral chest wall tissue excess.

Although the hips have been the most closely investigated area, zones of adherence are present throughout the body and are encountered during any body-contouring procedure. Inframammary folds and infragluteal folds are easily recognizable zones of adherence. The release of the crescent-shaped lower abdominal zone of adherence is of utmost importance during contouring of the abdomen and mons pubis.

Based on photographic evidence of massive-weight-loss patients, it appears that the human body has numerous, although perhaps less well circumscribed, zones of adherence that anchor the skin and subcutaneous tissue at various locations. These zones become more obvious in a morbidly obese or massive-weight-loss patient. These midabdominal, midflank, and midback zones of adherence are clinically significant in massive-weight-loss patients, because these pathologic zones of adherence need to be incorporated into excisional lifting procedures to create a smooth contour where there are folds and indentations.

Lymphatic System

Often considered the third circulation, the lymphatic system exists in parallel to the venous circulatory system. Lymphatic capillaries arise from the deep dermis and along muscle fascia, coalesce to form larger lymphatic vessels, and travel unidirectionally through a valvular system toward nodal basins (*arrows*) and lymphatic ducts. The lymphatic ducts drain the lymph fluid into the central circulatory system by entry into the venous circulation. Venous capillaries reabsorb approximately 90% of interstitial fluid, while the remaining 10% is transported by lymphatic channels.

The lymphatic system can be loosely divided in two configurations: the epifascial, superficial system that collects lymph from skin and subcutaneous tissues, and a deep system that collects from all subfascial structures. The superficial lymphatic system is a factor during body contouring at all tissue levels. The initial lymphatic capillaries are found in the dermal papillae, which form a superficial subdermal plexus of lymphatic sinuses. Histologically, these lymphatic capillaries are composed of endothelium on a discontinuous basement membrane without tight junctions. These initial lymphatic vessels coalesce into superficial precollectors in the dermis, which then coalesce into lymphatic ducts. Lymphatic ducts are differentiated from other lymphatic vessels by the presence of smooth muscle in the walls. Lymph flow and lymphatic contractility in the ducts increase in response to tissue edema, exercise, mechanical stimulation, and temperature changes.

The surgeon must recognize the anatomic relationship between lymphatic vessels and their surrounding structures to prevent lymphatic injury during surgical intervention, which could lead to lymphedema. Specific areas should be carefully dissected, particularly regions near major lymphatic ducts and/or nodes that are regional basins of lymph transport. The lymphatic system exists in parallel to the venous circulatory system, and injury to a major vein often coincides with injury to regional lymphatic ducts. Some degree of lymphedema is common and expected after body-contouring surgery, but prolonged or permanent lymphedema is an unfortunate outcome that is at least somewhat preventable.

Lymphedema is a progressive pathologic accumulation of protein-rich fluid in the interstitial fluid, leading to inflammation that causes adipose tissue hypertrophy and fibrosis. When protein in the interstitium increases tissue colloid osmotic pressure, additional fluid is driven into the interstitium. When lymphedema occurs in a limb, it can impair the functional capacity of that limb. Plastic surgeons commonly encounter secondary lymphedema from excision of lymph nodes, such as in breast cancer patients who have undergone axillary dissection. More often, lymphedema is encountered in body-contouring patients as a sequela of lymphatic transport after massive tissue excision.

Chronic lymphedema of the lower extremity is a common clinical entity that plagues even a svelte individual but can be especially pronounced in a morbidly obese person. Improvement in the appearance of lymphedema when treated with mechanical squeezing of the lower extremities suggests that lymphedema indicates a functional deficit of lymphatic transport rather than an absence of or a decrease in the number of lymphatic vessels. It is probably akin to venous stasis in that the conduits are present, but the valves are not propelling its contents forward.

There are lymphatic channels in the dermis and subdermal plexus and along muscle fascia. Interruption of lymphatic vessels is often cited as a worrisome complication of suction lipectomy, but clinical experience indicates otherwise. Lower extremity suction lipectomy without excisional surgery (with a 3-month follow-up) was not shown to cause a significant change on lymphoscintigraphic examination. Liposuction without excision probably does not permanently damage the lymphatic system, and temporary reduction in lymphatic drainage could be explained by postoperative edema that compresses the lymphatic vessels. In contrast, a study by Moreno and colleagues of patients after medial thighplasty showed that at the 6-month postoperative visit, 30% of patients exhibited abnormal findings on lymphoscintigraphy compared with their preoperative scan. This study demonstrated that excisional surgery, in contrast to suction lipectomy, can cause enduring anatomic and functional changes to the lymphatic system.

The nodal system is a pit stop for lymphatic fluid before it joins the venous circulatory system: the node basins allow passage of lymph fluid while trapping foreign particles. Chronic lymphedema of the upper extremity after axillary nodal dissection is caused by an absence of basins for lymph fluid from the affected extremity. The lymphatic vessels are present and probably still functional, but an absence of nodal basins causes a backflow of lymphatic fluid. However, clinically significant lymphedema occurs in a minority of axillary dissection patients, suggesting that even in the absence of nodal basins, lymphatic channels have direct connections to the ducts that drain into the venous circulation. Prolonged edema of the arm is reported rarely with brachioplasty, suggesting that disruption of lymphatic channels through excision of the posteromedial arm is rarely destructive enough to cause chronic lymphedema.

The superficial lymphatic system is a unidirectional network of lymphatic vessels and nodes that transport excess interstitial fluid into the circulatory system. Although it is a valved system, lymph vessels are vulnerable to temporary changes in local physiology created by local inflammation and postsurgical edema as well as chronic changes, such as the tissue burden of morbid obesity or massive weight loss. During excisional surgery, it is crucial to avoid the large lymphatic structures that often run alongside veins as well as efferent and afferent lymphatic vessels adjacent to nodal basins. Chronic lymphedema can be an unfortunate complication of excisional lift body-contouring surgery, and patients should be educated about the potential for this complication.

Arms

Guerrerosantos' classification divides the upper arm into four surfaces: anterior, medial, lateral, and posterior. These surfaces are defined with the arms hanging loosely at the sides, with the medial surface defined as the surface resting against the thorax. A common error in planning can make a scar too posterior, rendering it visible with the arms at rest. With aging or weight fluctuations, the laxity of the skin and soft tissues in the posterior proximal arm results in unsightly tissue redundancy. In patients of all weights, subcutaneous fat is most abundant in the posterior aspect of the proximal arm. After massive weight loss, excess skin and often excess adiposity persist.

During brachioplasty, the structures most at risk for damage are the intercostobrachial, medial brachial cutaneous, and medial antebrachial cutaneous sensory nerves. The medial antebrachial cutaneous nerve penetrates the deep fascia of the forearm at an average of 14 cm proximal to the medial epicondyle, becoming a superficial structure. The anatomic study by Knoetgen and Moran showed that the range for this distance was 8 to 21 cm and that the nerve did not run consistently with the basilic vein. The course of this nerve is variable, but it does reliably run in close proximity to the intermuscular septum. Careful dissection around this area can drastically reduce the likelihood of injury to this sensory nerve as well as to the basilic vein. The medial brachial cutaneous nerve runs posterior to the basilic vein and is at risk for injury if posteriorly placed incisions are used. The cephalic vein, which is superficial to the deep fascia throughout the arm, is generally safe from injury, as are superior lateral brachial cutaneous nerves, inferior lateral brachial cutaneous nerves, posterior brachial cutaneous nerves, and posterior antebrachial cutaneous nerves.

The preferred placement of incisions varies among practitioners; some surgeons favor a medial incision in the bicipital groove, whereas others choose posterior placement. Current designs in brachioplasty remove an ellipse of skin and soft tissue from the posterior arm as well as skin and soft tissue from the axilla. The dissection is superficial in the axilla and is unlikely to be in proximity to any vital structures.

According to Lockwood, the SFS of the arm has two distinct layers. First is the inherent SFS present throughout the rest of the body that encases and supports adipose tissue, undergoing stretching and relaxation with weight fluctuation and age. The second component is a longitudinal fascial system, or suspensory ligament, that extends from the inherent SFS to insert into the clavicopectoral and axillary fascia. Loss of tension in this suspensory portion of the SFS is most responsible for the ptosis of the posteromedial arm that is frequently seen in massive-weight-loss patients. Fascial anchoring of the suspensory ligament into the axillary and clavicopectoral fascia during brachioplasty to recreate this sling is crucial to performing a recontouring and rejuvenating procedure rather than a simply reductive procedure.

The suspensory ligament attachment to the axilla defines an important zone of adherence of the SFS to the underlying muscular fascia. Re-creating this zone of adherence produces a youthful axillary contour. After resuspension of the SFS in the axilla, the resulting zone of adherence should be concave compared with the posterior arm, with a sharp near-right angle when the arms are held in 90-degree abduction.

Small lymphatic vessels of the arm are distributed evenly and circumferentially throughout the arm. Anatomic studies have shown that large groups of superficial lymphatics are concentrated along the course of the basilic vein. A fair amount of skin and soft tissue reduction is performed in close proximity to the basilic vein during standard brachioplasties. Despite this, postoperative chronic lymphedema of the arm is rare in these patients, suggesting that the high concentration of lymphatic vessels in the rest of the arm can compensate for the vessels transected during brachioplasty.

Chest

Breast tissue is often severely affected by massive weight loss from relaxation of connective tissue layers, involution of breast parenchyma, and resulting skin excess. Lockwood described an anterior SFS layer of the breast as an indistinct connective tissue layer that lies between the dermis and the breast parenchyma, and the posterior SFS as the connective tissue fibers that travel through the breast parenchyma to attach to the pectoralis fascia. SFS fibers of the breast are not easily identified intraoperatively,

but should theoretically be a strength layer that encases the breast parenchyma. The suspensory ligaments of the breasts are called *Cooper's ligaments*; it appears that Cooper's ligaments are synonymous with Lockwood's SFS of the breast. The description differs in that Lockwood characterizes the anterior SFS layer as being somewhat separate from the posterior SFS throughout the parenchyma.

In massive-weight-loss patients the SFS is effaced, and the suspensory qualities of the SFS fibers are lost. Parenchymal reshaping techniques that rely on anchoring large areas of deepithelialized tissue to the periosteum of the rib or pectoral fascia are often more successful in massive-weight-loss patients with severe breast deformities. These techniques correct the vertical descent of the breast tissue and restore volume by resuspending, rather than excising, the descended breast tissue. There is often a large roll of soft tissue excess in the lateral chest wall in continuity with the breast. These soft tissue rolls can be deepithelialized and rotated medially on a random-pattern blood supply to augment the breast tissue.

Even in massive-weight-loss patients with the most severe deformities, the inframammary fold is usually intact. In most body-contouring surgeries, it is crucial to preserve the inframammary fold as the single most important zone of adherence in the upper trunk. Boutros et al performed a study to elucidate the anatomy of the inframammary fold. Through histologic evaluation, it was determined that the dermis of the inframammary fold houses regular arrays of horizontally oriented collagen fibrils. The arrangement is consistent through all layers of the dermis and is especially prominent in the papillary dermis. On gross examination, the SFS at the inframammary fold is condensed and thick, directly connecting the dermis to the pectoralis fascia below. The authors concluded that the inframammary fold is an intrinsic dermal structure consisting of regular horizontal arrays of collagen held in place by a zone of adherence formed by the SFS.

The symmetry of the inframammary fold is important in male body contouring as well, particularly because the inframammary fold is always visible in the normal male chest. In male chest contouring, the location of the horizontal scar for excision can lie at the inframammary fold. A well-placed horizontal scar can create the illusion of an inframammary fold, even without actual fascial attachments. The male inframammary fold should be located 4 to 5 cm inferior to the edge of the areola.

Lymphatic drainage of the chest wall is seldom problematic because of the proximity of tissues to the axillary nodes and the major lymphatic ducts, including the thoracic duct. Although some lymphatic flow through the nipple-areola complex is disrupted during breast-contouring procedures, the preservation of a dermal pedicle appears to provide adequate efferent lymphatics.

Trunk and Mons

The anterior trunk aesthetic unit comprises the abdomen, flank, and the mons. The abdominal wall is bound superiorly by the costal margin and inferiorly by the pelvic girdle. The umbilicus lies at the junction of the midline and the horizontal line drawn at the upper margins of the iliac crests. The natural waist is defined by a multilayer muscular suppression, which is approximately 1 inch above the umbilicus.

Sex differences in regional adiposity of the abdomen are well established. In general, women have a more protuberant anterior abdomen, and the adiposity is more pronounced in the inferior umbilical region. In men, the anterior abdomen is flatter and has a less pronounced flare at the iliac crest. With obesity, men tend to deposit more fat within the muscular envelope and in the flanks region compared with women. With massive weight loss, the sex differences are somewhat blunted, hidden beneath large areas of excess tissue. Ideally, body contouring should make the sex difference more pronounced, restoring masculinity and femininity to the patient's contours.

Both superficial and deep systems contribute to the blood supply of the anterior abdominal wall. Recent CT angiography and venography studies have revealed that perfusion of the soft tissue of the abdominal wall occurs through the subdermal and suprafascial plexus. The blood supply of the abdomen has been elucidated in multiple anatomic studies. The deep vascular supply to the abdominal wall comes from the following:

- The deep inferior epigastric artery and deep superior epigastric artery, which is an extension of the internal mammary artery. The vessels anastomose on the deep surface of the rectus abdominis muscle between the umbilicus and the xyphoid.

- The deep intercostal arteries T6-12, which travel in the plane between the transversus abdominis and internal oblique muscles, then join the central vasculature of the deep epigastric vessels at the semilunar line.

- The inferomedial to superolateral axis includes the deep circumflex iliac artery, which anastomoses with the lower intercostal and lumbar arteries.

The superficial blood supply consists of a network of connections between the inherent superficial vessels and the musculocutaneous perforators from the deep system:

- The superficial circumflex iliac artery, which supplies the inferolateral abdominal skin and anastomoses with superficial branches from the intercostal vessels and perforators from the deep circumflex iliac system. This is divided during an abdominoplasty or other truncal excision procedures.

- The superficial inferior epigastric artery, which supplies the inferomedial abdominal wall and always runs superficial to Scarpa's fascia. This vessel is present in 80% of patients. The vessel forms an anastomotic network with the su-

perforating branches from the deep inferior epigastric artery, the lateral thoracic artery, and superficial branches of the intercostal arteries.

Intercostal musculocutaneous perforators at the level of origin of the external oblique muscle.

Musculocutaneous perforators from the superior and inferior deep epigastric arteries, the deep circumflex iliac artery, including the superficial superior epigastric artery, which enters the superomedial abdominal wall through the upper rectus abdominis muscle. The lateral branch of the superficial superior epigastric artery runs along the eighth costal cartilage and anastomoses with the eighth intercostal artery.

After abdominoplasty and other excisional truncal contouring surgeries, the superficial inferior epigastric perforators from the deep inferior epigastric artery and the superficial circumflex iliac arteries are divided. Flap survival depends on the superficial perforators of the intercostal musculocutaneous perforators and the superficial branches of the superior epigastric artery. The anastomoses between the deep circumflex iliac artery and the lower superficial intercostal vessels augment the flap supply; however, these anastomoses are divided during circumferential body contouring. Dye studies have revealed that the blood supply of the inferiormost portions of the abdominal flap is random, and any tension in the midline inferior margin can lead to skin and soft tissue necrosis.

The intercostal perforators and the subdermal and suprafascial plexus must be protected to ensure the viability of the abdominal flap after excisional contouring. With preservation of the superficial blood supply, abdominoplasty with deep plane resection of subscarpal fat can be safely performed in most patients. Lipoabdominoplasty—an abdominoplasty with selective undermining with liposuction of abdominal wall and flanks—has a low incidence of ischemic complications as a result of superior preservation of the blood supply.

Manipulation of the SFS is particularly significant in truncal contouring. Scarpa's fascia is the primary strength-retaining portion of the SFS network. Scarpa's fascia is congruent with Colles' fascia in the perineum. The deep fascia (innominate fascia, fascia of Gallaudet) that is adherent to the musculoaponeurosis is continuous with the fascia lata of the thigh. After excisional body contouring, the SFS must be resuspended to maintain the new contour. Frequently this means deep suspensory sutures tacking the SFS to the deep fascia in the desired location, creating a new zone of adherence with suture anchors.

The musculoaponeurosis of the abdomen, consisting of the external oblique, internal oblique, and transversus abdominis muscles, which envelope the anterolateral wall of the abdomen, and the aponeuroses of these muscles make up the anterior and posterior leaves of the rectus sheath. Relaxation of these aponeurotic connections within the rectus sheath creates the various diastases seen in the abdomen, especially in multiparous women. The aponeurotic layers coalesce at the midline, creating the linea alba. Frequently in multiparous women, there is significant relaxation of the midline aponeurosis, containing a rectus diastasis. During truncal-contouring procedures, various maneuvers may be performed to address relaxations in the aponeurotic layer. Vertical supraumbilical and infraumbilical figure-of-eight sutures are placed to close areas of diastasis. Horizontal or oblique imbricating sutures can narrow areas of true diastasis or aponeurotic excess.

Superficial lymphatic vessels of the abdominal wall drain into two systems. The lower-half lymphatics coalesce into trunks that drain into the superficial lymph nodes of the groin, whereas the upper abdomen vessels drain, along with the chest wall, into

the axillary nodes. Long-standing edema in the abdominal wall after an abdominoplasty or other excisional trunk procedure of the abdomen could be caused at least in part by the lack of lymphatic channels that drain the inferiormost part of the abdominoplasty flap. Residual postoperative edema in the tissues likely compresses existing lymphatic capillaries, preventing transport of interstitial fluid. Lipoabdominoplasty, which minimizes direct excision of soft tissue and instead uses suction-assisted lipectomy to debulk the abdominal wall, probably preserves a greater number of lymphatic vessels initially, resulting in improved contour and a decreased incidence of seromas.

Anatomic studies have delineated the presence of superficial lymphatic vessels at the fascial layer, but the nature of the connection of these two systems in the subcutaneous fat remains somewhat obscure. In general, it is likely that the initial swelling seen after any excisional body-contouring procedure is caused by the disconnection of lymphatic channels and lymphatic-venous anastomoses in the area of excision and dissection. The eventual improvement in edema suggests that there is some degree of lymphangiogenesis. Intervening infection or fat necrosis can cause scarring in the subcutaneous tissue, making it difficult for new channels to develop. Compression garments activate lymphatic ducts and temporarily improve their efficiency. One can extrapolate that panniculitis in the dependent abdominal tissue after massive weight loss may be not cellulitis but lymphangitis: inflammation of poorly mobilizing or stationary lymphatic fluid.

In the lower abdomen, leaving Scarpa's and subscarpal tissue intact above the mons to a height of approximately 3 fingerbreadths below the umbilicus will leave most of the lymphatics directly above the mons intact, allowing better control of postoperative lymphedema. Scarpa's fascia from below is then affixed to superficial rectus fascia at approximately the height of the umbilicus to create a lifting effect for the mons pubis and upper medial thighs.

No changes in sexual sensation will occur if mons fat is removed superior to the pubic symphysis and if labia majora fat is excised lateral to the pubic symphysis and clitoral hood. Anchoring the excised superior edge of pubic skin succeeds in creating a *de novo* zone of adherence and preventing further mons ptosis.

The pathophysiology of abdominal excess encompasses skin excess, striae/rash, thinned dermis, and attenuated SFS fibers, including Scarpa's layer. In massive-weight-loss patients, the excess abdominal tissue can be compromised by chronic lymphedema, rash, and panniculitis. In contouring the trunk, several anatomic principles must be adhered to:

The umbilicus should be anchored to the proper position and the inferior abdominal wall anchored to create a new zone of adherence.

The SFS fibers should be encompassed in lifting maneuvers to create a new contour.

Initial deterrence in lymphatic outflow should be expected to some degree, and postoperative compression can increase interstitial pressure, preventing lymphatic fluid from becoming static in the subcutaneous tissues.

The vascular supply to the newly contoured abdomen comes from the superolateral abdomen through the intercostal perforators; the midline inferiormost tissue is random in blood supply.

The lateral cutaneous branches of the iliohypogastric and intercostal nerves are at risk for entrapment, particularly during a circumferential body lift. Aggressive lateral plication of the external oblique muscle for waist definition can increase the risk for nerve entrapment.

Hips

Patients frequently express concern about their hips and flanks, although hips are more likely to have excess adiposity in women, whereas the flanks are more frequently a problem area in men. The hips and flanks have a continuation of the SFS, with superficial fat above Scarpa's layer encased in more closely related vertical SFS fibers, while fat below Scarpa's has fewer fascial fibers and the fat appears more mobile. The boundaries of the deep fat compartments are defined by zones of adherence.

The zone of adherence, as described by Lockwood and further defined by Rohrich et al, describes sex-specific areas of fascial attachments where the superficial, more dense SFS fibers send direct attachments to the muscle fascia below, creating a boundary between two fat compartments and creating an area of defined contour. In men's hips, the zone of adherence is along the iliac crest, whereas in women, the zone of

adherence of the hip is below the iliac crest. The fat compartments create a slight bulge both superior and inferior to this zone of adherence, even in normal-weight women. In overweight and even in many normal-weight women, excess fat deposited laterally below this zone of adherence imparts an unsightly saddlebag deformity. In men, the lateral deposits of fat are more frequently found above the zone of adherence, creating flank adiposity referred to as “love handles” or a “spare tire.” Contouring in this area frequently involves selective liposuction above and below the zone of adherence, since interruption of the zone of adherence will not correct a contour deformity caused by excess adiposity.

In massive-weight-loss patients the skin excess is often circumferential, and patients of both sexes will have contour deformities both above and below the hip zone of adherence. A lower body lift and other associated excisional lifting procedures actually remove the fascial attachments that previously defined a zone of adherence. A zone of adherence is, to begin with, less well defined and lax in this population. By lifting and reanchoring soft tissue above a prior zone of adherence, a *de novo* artificial zone of adherence is fashioned.

Buttocks

Senescent changes and changes from massive weight loss have very similar effects on buttock contours, including a loss of adipose volume, ptosis of soft tissue and skin, increased hip width, and lengthening and flattening of the gluteal fold. Central adiposity in the lower back increases with age and blunts the trunk-gluteal angle, further contributing to loss of projection. All these changes combine to create a buttock that appears flat, square, and in women, less feminine.

The buttocks in a massive-weight-loss patient appear hypoplastic. The deformities include loss of gluteal projection; effacement of the lower back/gluteal sulcus; loose, misshapen buttock skin; lateralization and inferior displacement of the remaining soft tissue; and a lax gluteal fold. In addition, the central crease and inferior gluteal crease droop. Midline skin and soft tissue should be excised as part of the lower body lift to recreate a more pleasing gluteal cleft without surrounding excess tissue.

Centeno and Young defined the eight gluteal aesthetic units: two flank units, the sacral triangle, two buttock units, the infragluteal diamond, and two symmetrical thigh units. Buttock reshaping is best achieved by enhancement of the buttock units in conjunction with reshaping and reduction of the other aesthetic units.

Anatomic landmarks in aesthetic surgery of the buttocks have been well summarized; these are the sacral triangle, sacral dimples, trochanteric depressions, posterior iliac crest, coccyx, and gluteal folds. The sacral dimples are created by the confluence of the posterior superior iliac spines, lumbosacral aponeurosis, and the insertion of the gluteus maximus and define the superior medial border of the buttock. The sacral triangle is defined by the bilateral sacral dimples and the coccyx, and liposuction of the triangle can further augment the protuberance of the buttock cheeks.

Traditional excisional lower body lifts significantly improved buttock contours but failed to correct the loss of gluteal projection, which often imparted an unfeminine, flattened buttock. Recently, gluteal contouring has focused on raising large deepithelialized flaps based on the superior gluteal artery perforator, anchoring the tissue beneath the superior and interior flaps of a lower body lift. This retains volume in combination with skin excision to create a tighter, more protuberant buttock. Various designs and techniques have been described, including island, mustache, and rotational flaps. In each case, the goal is to add projection and volume to the buttocks while diminishing the adjacent gluteal aesthetic areas. *One cannot overemphasize the importance of not interrupting the natural infragluteal fold, which will shorten in appearance with excision and lifting of superior redundant tissue.*

The deepithelialized gluteal flap is isolated on two major perforators from the superior gluteal artery and rotated in a superomedial direction to augment gluteal projection. To identify the superior gluteal artery perforators, a line is drawn from the posterior iliac spine to the greater trochanter, and the two major perforators are identified 6 to 9 cm from the midline along this line. These vessels send forth large musculocutaneous perforators that can be easily identified during suprafascial dissection.

Anchoring of the SFS of the inferior flap in a lower body lift to the muscular fascia plays a significant role in achieving the initial contour. The gluteal fold is a natural

zone of adherence but can appear effaced or discontinuous after massive weight loss. The zone of adherence must not be disrupted to avoid creating a new deformity.

During circumferential body lifts, the cutaneous branches of the iliohypogastric nerve, the superior cluneal nerves L1-3, and the dorsal rami of sacral nerve roots 3 and 4 are at risk. Permanent changes to protective sensations may occur, and this potential morbidity should be discussed with the patient preoperatively.

Thighs

Relaxation of the SFS fibers in a negative vector combined with excess adiposity can lead to a ptotic appearance of the medial thigh as an individual ages or undergoes massive weight loss. In postbariatric patients, a tremendous amount of excess skin and subcutaneous tissue can lead to an extra soft tissue roll in the medial thigh. Recent articles have noted that much of the excess in the medial thigh after massive weight loss is vertical rather than horizontal. Because of this, the great majority of thighplasties in the postbariatric population require a vertical scar.

In medial thighplasty, the lifted portion of the medial thigh tissue must be anchored to the Colles' fascia of the perineum to prevent scar migration and early recurrence of ptosis. The anchoring sutures should also create a well-defined perineal-thigh crease. This is another way linear and sequential anchoring of the SFS can create new, well-defined topographic marks with little or no excess tissues blurring the anatomy. Colles' fascia attaches to the ischiopubic rami of the bony pelvis; anteriorly it is continuous with Scarpa's fascia; and posteriorly it fuses with the urogenital diaphragm. At the junction of the perineum and the medial thigh, this layer is clearly identifiable by dissecting to the origin of the adductor muscle on the ischiopubic ramus and retracting the skin and subcutaneous tissues of the vulva medially.

Anatomic studies reveal that 80% of lymph vessels run into the inner surface of the thigh, 20% on the lateral surface. Because of the risk of significant chronic edema after a medial thighplasty, some authors advocate leaving a layer of subcutaneous tissue along the muscle fascia of the area of resection, not completely resecting the lymphatic vessels in the area. Significant incisions and tissue excisions are also made away from veins, which are the natural accompanying structures of the lymphatic vessels. Anatomic studies show that around the thigh and groin area, the lymphatic ducts are concentrated around the greater saphenous vein, while in the lower leg the lymphatic ducts are more evenly distributed circumferentially around the leg. This suggests that interruption of tissues around the greater saphenous vein should be minimized to decrease the potential for trauma to the lymphatic ducts of the thigh and groin. The area anterior to the greater saphenous vein is particularly susceptible, with an afferent "bottleneck" visualized in anatomic studies.

In summary, the medial thigh is an unforgiving area for the plastic surgeon because of poor tissue quality, a high concentration of lymphatic vessels, the risk for scar migration and vulvar deformation with soft tissue anchoring, and the pain associated with anchoring sutures in the perineum. Although associated with discomfort and sometimes deformation of the vulva, a medial thighplasty is unlikely to be successful without strategic anchoring of thigh tissues to Colles' fascia. Careful preservation of the lymphatic vessels can help to reduce postoperative edema.

Knees and Legs

A natural zone of adherence occurs along the area at which the quadriceps muscle's aponeuroses coalesce along the upper edge of the patella. Fullness at the knee is often from the bulk of the quadriceps femoris as well as the medial muscle group containing the gracilis, sartorius, semitendinosus, and semimembranosus muscles. Commonly there is a localized pocket of adiposity overlying the medial muscle group. Excess fat around the knee is considered a particularly displeasing problem for women for which there is no good solution. In massive-weight-loss patients, a pannuslike envelope of skin and soft tissue can drape over the superior knee zone of

adherence. Although direct excision leaves an unsightly scar, the procedure has been performed. Often medial thighplasties incorporate a vertical scar that extends to the knee, creating some lifting and thinning in the medial aspect of the knee.

The anatomic basis for an undesirable silhouette is often muscular, making it more difficult to treat with traditional methods of liposuction and excisional lifting procedures. A bulky calf is often caused by a large gastrocnemius muscle proximally and the soleus muscles, particularly in the distal two thirds of the leg. The desired slender leg silhouette from calf to ankle is often obliterated by a wide, thick distal soleus, or a natural fullness of the lateral compartment muscles, particularly the peroneus brevis anterolaterally, and the flexor digitorum longus muscles posteromedially. A combination of undesirable muscle bulk and excessive length, along with excess tissue from massive weight loss, can cause an unattractive leg shape.

Fat distribution over the lower leg, except for a lack of fat over the anterior tibia, shows a pattern that is diffuse and circumferential. For these anatomic reasons, lower extremity contouring remains one of the greatest areas of challenge.

Ankles and the lower extremities are the anatomic areas most susceptible to lymphedema. Lower extremity lymph vessels eventually coalesce and merge into the superficial groin lymph nodes, making them the longest traveling lymphatic system in the body. With age and obesity, chronic lymphedema from an inactive or underactive lymphatic system is already likely to be present at baseline, and no doubt contributes to some degree to effacing the contours. Suction lipectomy must be used with utmost caution in the ankle and lower extremity, and with the expectation that long-term use of compressive garments will be essential to decrease lymphedema.

Recent cadaveric studies suggest that injection of tumescent fluid and longitudinal rather than transverse movement with the suction cannula decrease damage to lymphatic vessels. This is especially crucial in lower extremities with preexisting lymphedema and in zones of high concentration of lymphatic vessels within a narrow zone, such as the medial knee.

Concluding Thoughts

In the past, much of the discussion in applied anatomy of body contouring concerned neurovascular structures, musculoaponeuroses, and regions of adiposity. Although knowledge of blood supply and adjacent nerve structures is crucial, we think that understanding the roles of SFS, zones of adherence, and lymphatic drainage in the superficial subcutaneous tissue can help to elucidate problem areas in body contouring and aid in the innovation of new therapies.

Clinical Caveats

The SFS is a subdermal soft tissue scaffold that exists throughout the body; it encompasses adipose tissue and imparts biomechanical strength to surgical repairs.

Pathologic conditions of the SFS are partially responsible for cellulite, ptosis, and the large overhanging soft tissue rolls seen in massive-weight-loss patients.

Incorporation of the SFS in surgical repair is particularly important in parenchymal reshaping and excisional lifting techniques of body contouring.

The zones of adherence are pathologic and sometimes displaced in postbariatric patients.

Zones of adherence are often interrupted during excisional body contouring, and anchoring and suspension of tissues are important to prevent tissue descent.

Violation of certain zones of adherence (inframammary fold, gluteal fold) can lead to secondary deformities that are challenging to correct.

Lymphatic vessels are found in the deep dermis, subdermal plexus, and along muscle fascia.

Interruption of lymphatic channels through excision can cause chronic edema in surgical zones, particularly if a nodal basin is interrupted.

Liposuction causes temporary slowing of lymphatic drainage but does not cause permanent damage to lymphatic vessels.

Annotated Bibliography

Warren AG, Bronson H, Borud LJ, et al. Lymphedema: a comprehensive review. *Ann Plast Surg* 59:464-472, 2007.

The authors review the diagnostic and treatment modalities for lymphedema. The utility of various imaging modalities is discussed. Initial treatment with decongestive lymphatic therapy can provide significant improvement in patient symptoms and volume reduction of edematous extremities. Surgical treatment with circumferential liposuction is explored.

Lockwood TE. Superficial fascial system of the trunk and extremities: a new concept. *Plast Reconstr Surg* 87:1009-1018, 1991.

This study first defined the superficial fascial system as being composed of all connective tissue between the dermis and muscle fascia. Understanding the structural anatomy of the system allows us to understand the changes in body contour with age and adiposity. Fresh and cadaveric dissections were used to characterize SFS appearances across

gender, region, and degree of adiposity. Manipulation of the SFS provides the anatomic basis for surgical lifting techniques in body contouring.

Markman B, Barton FE Jr. Anatomy of the subcutaneous tissue of the trunk and lower extremity. *Plast Reconstr Surg* 80:248-254, 1987.

The authors attempted to shed light on the anatomy of the subcutaneous tissue in the trunk and lower extremity using fresh and embalmed cadaver dissections and CT scans. Diagrammatic comparisons of the subcutaneous adipose tissue are presented, showing differences in both adiposity and density of connective tissue fibers between regions. The anatomic basis for deep plane liposuction is also discussed.

Song AY, Askari M, Azemi E, et al. Biomechanical properties of the superficial fascial system. *Aesthet Surg J* 26:395-403, 2006.

Through a series of biomechanical tests of both human and porcine models the authors demonstrated that the SFS is a connective tissue strength layer independent of the dermis. They also performed tissue dissections that characterized the dermis-SFS junctions as a continuous collagen and elastin bridge. The porcine model suggested that permanent sutures in the SFS layer may enhance the biomechanical strength of the repair.

Rohrich RJ, Smith PD, Marcantonio DR, Kenkel JM. The zones of adherence: role in minimizing and preventing contour deformities in liposuction. *Plast Reconstr Surg* 107:1562-1569, 2001.

The authors expanded on Lockwood's observations of anatomic zones of adherence of the SFS that divided the subcutaneous tissue into compartments. These zones bring the subcutaneous fat into a shallower layer, making these areas more susceptible to dimpling and contour deformities during liposuction. The importance of avoiding these zones is emphasized.

CHAPTER 76

Clinical Decision-Making in Body Contouring

FOAD NAHAI

*It's all about the skin.
It's all about safety.*

The advent and increasing popularity of liposuction over the past 30 years not only revolutionized but also forever changed body contouring. Even today, the tremendous impact of liposuction is influencing the further evolution of body-contouring procedures. The incorporation of liposuction has not only made body contouring safer, faster, and possible with minimal scarring, but also liposuction has been the most common of all aesthetic surgical procedures for several years running, according to the American Society for Aesthetic Plastic Surgery (ASAPS) statistics, only to be displaced to number two by breast augmentation in recent years. Most notable, however, is the fact that through liposuction, body contouring has become an option to many who would not otherwise have considered it because of the obligatory long scars.

Not all those who seek body contouring are candidates for liposuction as their ideal procedure. It is very disappointing to have to explain to a patient why he or she is not a candidate for liposuction. Although contraindications and relative contraindications to liposuction, such as morbid obesity, intercurrent cardiac disease, or endocrinologic disease apply to all forms of body contouring, in reality the major reason that most patients are not “ideal” or the “best” candidates for liposuction relates to the quality and quantity of their skin.

Whether we are discussing short-scar face lift, short-scar breast surgery, or body contouring through liposuction, the limiting factor is skin quality and skin quantity. Inelastic, stretched, poor-quality skin will not redrape or contract and must be excised.

Evaluation of the skin is the key to decision-making in body contouring. Once the surgeon has decided that skin quality or skin quantity is such that it will redrape, in most patients and in most anatomic areas liposuction alone will be the procedure of choice. If the surgeon decides to resect skin, the location and length of the incision are determined. The decision as to the exact method of skin resection—a single-stage versus a multistage procedure—must also be made at this time.

Patient Evaluation and Counseling

When I greet a new patient who is interested in body contouring, one of the first questions I ask is, “Would you like to look better in your clothes, or in and out of your clothes?” Most younger women answer that they wish to look good in and out of their clothes, especially in bikini bathing suits. Older women and most men reply that they would like their bulges improved so that they appear more shapely and better contoured in their clothes. The patients’ goals and expectations of the result are a useful guide to me. I then examine them and make recommendations. We must balance the goals and their vision of the results against the realities of their tissues, especially their skin. I try to establish whether the patient is seeking reshaping or reshaping and skin tightening.

After I examine the patient, which includes evaluating the skin and fat, we discuss the patient’s options. The options and decisions are straightforward in patients who are ideal candidates for liposuction. Similarly, for those who obviously require skin excision, the options and decisions are straightforward. However, for a group of patients between these two extremes, a complex discussion concerning skin excision is entertained. The tradeoff is a longer scar with skin and soft tissue excision and a better result, versus a minimal scar from liposuction, recontouring without skin improvement, or even a worsening of skin laxity and the appearance of skin folds. Another issue to consider is the risk-benefit ratio of the more complex procedures. For some patients in this middle group, the risk of more extensive surgical procedures

may not be justified by improved skin tightening. Patient safety, morbidity, and length of recovery should all be taken into account in the decision-making process. Obviously, the expense of the procedures is another issue that may be more important to some patients than to others. Clearly, liposuction is less time consuming and less expensive than resectional body-contouring procedures.

These factors must be borne in mind and openly discussed with patients before embarking on expensive body-contouring procedures, especially in patients who have experienced massive weight loss. These patients present a special challenge to the aesthetic surgeon in that extensive skin resection and recontouring procedures may be needed in all anatomic areas. The question of single-stage versus multistage procedures is an important consideration. Although a single-stage procedure obviously will be less expensive and perhaps more appealing to more patients, this should be balanced against the increased risk posed by prolonged surgical procedures in this group of patients.

Balancing the quality of the result with safety, scars, and cost

Decision-making in body contouring, especially for massive-weight-loss patients, must take into account the balance between the quality of the results and safety issues. Ultimately, cost should not factor into a final decision about the procedure.

Abdominal Contouring

Abdominal-contouring procedures range from liposuction to circumferential abdominoplasty combined with a body lift.

The first patient (*left*) is a suitable candidate for liposuction; the second patient (*center*) requires an abdominoplasty; and the third patient (*right*) is best suited to full-body contouring, including a circumferential abdominoplasty and body lift.

Abdominal Contouring Evaluation Checklist

- Skin
- Fat
- Muscle and fascia
- Adjacent areas

Evaluation and classification of abdominal changes precedes decision-making and the selection of the appropriate operation. The skin, fat, and musculofascial contour have traditionally been the three major components to be assessed; however, we do not evaluate and treat the abdomen in isolation, especially in massive-weight-loss patients. To these three major components we now add a fourth: assessment of the adjacent areas, including the thighs, flanks, and back. These four primary components of abdominal changes assist in classifying the severity of the problem and selection of appropriate treatment. Most patients fall into one of the four categories.

Classification of Abdominoplasty Candidates				
	Class 1	Class 2	Class 3	Class 4
Skin excess	None—minimal	None—minimal	Moderate-severe	Severe
Skin elasticity	Normal	Normal	Poor	Poor
Fat excess	Mild-moderate	Mild-moderate	Moderate-severe	Moderate-severe
Musculofascial contour	Normal	Abnormal	Normal or abnormal	Normal or abnormal
Adjacent areas	Normal	Normal	Normal	Abnormal

Skin

We assess the quality and quantity of the abdominal skin. We assess the quality and elasticity through observation for stretch marks and the pinch test, in which the skin is pinched and pulled away from the underlying subcutaneous tissues; during the pinch test, we look for elasticity and recoil as indicators of retraction and redraping after surgical intervention. We also look for scars that may affect liposuction or be improved through excision with open abdominoplasty procedures. We also look for excess skin above and below the umbilicus, for umbilical hooding, which is an indication of periumbilical skin excess, and for loss of skin elasticity.

Skin Evaluation Checklist	
Skin quality	Skin excess
– Stretch marks	– Below umbilicus
– Pinch test	– Above umbilicus
– Scars	– Umbilical hooding

Fat

The amount of excess fat and its location are noted. In general, larger volumes of excess fat are usually seen with excessive amounts of poor-quality stretched skin and striae requiring excision. Smaller and more moderate volumes of fat are amenable to liposuction as long as the skin is suitable. The location of the fat above and below the umbilicus and flanks is noted.

Musculofascial Contour

The patient is examined while standing and recumbent. The muscles and fascia above and below the umbilicus are evaluated. With the patient standing, the general appearance and protuberance of the abdomen are noted. The patient is asked to relax and to tighten the abdominal muscles so abdominal wall strength and integrity can be evaluated. Any abdominal weakness, diastasis, or hernia is noted. Then, with the patient lying down, the abdomen is again examined at rest and on straight-leg-raising, which contracts the abdominal muscles, making weakness, diastasis, and any hernia much more obvious. Extensive diastasis and hernias will have to be repaired to achieve flattening of the abdominal contour. If there is no abdominal protuberance, liposuction only may achieve the goal of flattening the abdominal contour. On the other hand, any diastasis or umbilical or midline ventral hernia will require open or endoscopic repair to effectively recontour the abdomen.

Adjacent Areas

In most patients after an isolated abdominoplasty, the recontoured abdomen blends in well with the adjacent areas, the upper thighs, hips, buttocks, flanks, and back, especially if the abdominoplasty is combined with some liposuction of the flanks. However, in an increasing number of patients seeking abdominal recontouring, especially after massive weight loss, the abdomen cannot and should not be dealt with in isolation. We therefore have to evaluate the adjoining areas—the thighs, flanks, hips, and back. If any of these areas require recontouring to restore balance to the patient's trunk, a combination of other procedures must be included with the abdominal operation. These will range from belt lipectomy to abdominoplasty combined with a body lift.

Patient Profiles

Class 1

Typically, class 1 patients have excess abdominal wall fat, often localized below the umbilicus, with normal fascia without laxity, diastasis, or herniation. The skin is of normal quality, with no excess. Ideally there should be no preexisting abdominal scars. These patients will have a good result after liposuction. No fascial tightening is needed, and any minimal skin excess will respond well to redistribution and contraction.

Class 2

Class 2 patients have normal-quality skin with minimal to moderate excess fat. They do not require skin excision, and the excess fat is amenable to liposuction. However, these patients have significant musculofascial laxity, which may include diastasis, midline ventral hernia, or umbilical hernia. These patients must have anterior abdominal wall plication to achieve maximum contour improvement.

I believe they are ideal candidates for endoscopic abdominoplasty as a first-choice procedure. A mini-abdominoplasty would be an acceptable alternative. Although some skin excision is possible through the lower abdominal excision with a mini-abdominoplasty, the primary role of the incision is access to the abdominal wall for repair. Through this incision, the infraumbilical abdominal wall is readily exposed and the repair of the fascia from the umbilicus down is easily accomplished. The umbilical stalk can be divided (umbilical float) to allow access to the upper abdomen for fascial repair above the umbilicus. Although this repair is possible through the mini-abdominoplasty approach, it is not easy.

In these patients, the advantages of the endoscopic approach include a much shorter scar, 4 to 5 cm in length, decreased postoperative pain and morbidity, and accurate repair of the fascia from the xyphoid process down.

Class 3

Patients in class 3 have moderate to severe amounts of excess skin of poor elasticity riddled with stretch marks; they also have moderate to severe amounts of excess fat. There may or may not be muscular or fascial weakness. Liposuction or an endoscopic or mini-abdominoplasty approach is not appropriate for these patients. They require a full abdominoplasty with resection of the excess skin and fat, with umbilical transposition. Liposuction may assist lateral contouring. A variety of incisions are available for the dermolipectomy in this group, and the final choice is a matter of patient and surgeon preference. However, the scar should be placed low enough and in such a position to avoid any unnatural elevation of the pubic hairline.

Class 4

Typically, class 4 patients have all the features of class 3 patients and much more: more skin and fat excess in the adjoining areas—the flanks, back, and thighs. Most if not all massive-weight-loss patients are in this category. An isolated abdominoplasty is not an appropriate procedure for class 4 patients; they are best treated through a combination of procedures that will include an abdominoplasty and thigh or body lift. Most patients in this category have undergone massive weight loss. In addition to routine preoperative tests, an assessment of nutritional status is essential in this group of patients.

Safety Issues

Abdominoplasty, in particular an abdominoplasty combined with a body lift, is one of the highest risk procedures that aesthetic surgeons perform. Patient safety is of paramount importance. The risks are minimized and patient safety is ensured through appropriate patient selection, patient preparation, assessment of nutritional state, and staging of the procedures, if necessary. Intraoperative precautions include deep venous thrombosis prophylaxis, expert administration of anesthesia, and limiting not only the length of the procedure but also the combination of procedures.

The risk of venous thromboembolism (VTE) is highest with abdominoplasty and increases further when abdominoplasty is combined with other procedures. Chemoprophylaxis should be considered for such patients.

ASSESSMENT OF ABDOMINAL FEATURES

Upper Arms

The options for recontouring the upper arms range from liposuction to the standard arm lift, with the long incision extending from the axilla to the elbow. An extended brachioplasty, which combines simultaneous excision of redundant posterior axillary fold tissue, is best suited for individuals who have lost massive amounts of weight. Selection of technique, as with almost all body contouring, is based on the patient's skin excess and skin quality. Individuals with excess fat but minimal or no skin excess and with normal skin elasticity are ideal candidates for liposuction. Their skin has enough elasticity to redrape and contract after liposuction. In these patients, my preference is ultrasound-assisted lipoplasty (UAL) over suction-assisted lipoplasty (SAL). The patient illustrated in the top image is a candidate for liposuction; the patient in the lower right image will require a full brachioplasty.

Patients with significant skin excess with loss of skin elasticity are clear candidates for brachioplasty with the classic incision. There is a small group of patients with excess fat who also have moderate skin excess with normal or minimal loss of skin elasticity. These patients may be candidates for a modified limited-scar brachioplasty combined with liposuction. In this group, the skin excision is limited to a horizontal excision within the axilla, with or without a short vertical extension along the medial border of the arm. I evaluate candidates for this modified approach by pinching and pulling the skin within the axilla and observing the effect on the arm. If the skin tightening appears sufficient and the patient, who observes this maneuver in the

mirror, indicates that he or she will be happy with such a result, then I would recommend this modified approach.

Thigh Lift

Options for recontouring the thighs range from liposuction to body lift combined with abdominoplasty.

The patient on the left, who has already had liposuction, has skin excess and skin irregularities, especially in the medial and distal thigh. She is a candidate for a medial thigh lift through a groin crease incision. The patient in the center is a candidate for abdominoplasty combined with a medial thigh lift, with the scar limited to the groin crease. The patient on the right represents the extreme; she is a candidate for a combined abdominoplasty, medial thigh lift, and body lift. In addition to the groin crease incision, the medial thigh lift will require a vertical skin excision and resultant scar along the medial surface of the thigh. The distinguishing factors among the three women are the volume of fat excess and the quality and amount of skin excess. The patient on the left has the least amount of excess fat, the least amount of excess skin, and the skin with most elasticity.

Liposuction

Ideal candidates for liposuction have minimal to moderate amounts of excess fat with minimal or no skin laxity or skin excess, and their skin will have normal or near-normal elasticity.

Medial Thigh Lift

The classic medial thigh lift scar in the groin crease extends from the anterior superior iliac spine along the inguinal ligament running adjacent to the labia majora or scrotum and ends in the gluteal crease. Through this incision, a variable-sized crescent of skin and excess fat is excised from the upper inner thigh with the maximal skin excision centrally located over the upper inner thigh. The best candidates are those with moderate amounts of fat and mild skin excess and laxity, especially involving the upper medial thigh. It is safe to combine this procedure with liposuction of the anterior thigh and knee, as needed.

Medial Thigh Lift Combined With Abdominoplasty

This combined approach is best for patients who have the thigh changes described previously, plus abdominal changes that require a full abdominoplasty. The lateral part of the thigh lift and abdominoplasty incision meets at the medial end of the inguinal ligament. The combined procedure results in improvement of the abdomen and thighs, especially the medial and anterior thigh. This procedure may safely be combined with liposuction of the anterior thigh and knee.

Medial Thigh Lift With Groin Crease and Medial Thigh Scar

Patients with extreme skin laxity and skin excess, especially along the medial thigh, will respond minimally to skin excision through the crescent at the upper end of the thigh. In addition to that crescent, they will require a variable amount of skin excision vertically along the medial axis of the thigh, a triangular skin excision with the base of the triangle placed superiorly.

This procedure can safely be combined with an abdominoplasty or with a full lower body lift. However, combining it with too many other body-contouring procedures may increase the risk and should only be undertaken on a highly selective basis. This procedure may be safely combined with liposuction of the anterior thighs.

Choosing the Best Option

Morphologic Changes	Thigh-Contouring Options			
	Liposuction Only	Medial Thigh Lift + Groin Crease Incision	Medial Thigh Lift + Abdominoplasty	Medial Thigh Lift + Groin Crease Incision + Medial Vertical Scar
Fat Excess				
Moderate				
Extreme				
Skin Quality				
Normal elasticity				
Poor elasticity				
Skin Quantity				
No excess				
Moderate				
Extreme				
Adjacent Areas				
Normal contour				
Requires recontouring				

Clinical Caveats

The patient's goals and expectations must be matched with the realities of his or her tissues.

Decision-making in body contouring, especially for massive-weight-loss patients, requires taking into account the balance between the quality of the results and safety issues.

Recontouring must be distinguished from skin tightening.

Skin, fat, muscle, fascia, and adjacent areas are evaluated before selecting procedures for abdominal contouring.

Body contouring in a massive-weight-loss patient is a high-risk procedure.

Multiple procedures may need to be staged to minimize risk.

The patient's nutritional state should be assessed, especially in massive-weight-loss patients.

Chemoprophylaxis is important for massive-weight-loss patients and when combining abdominoplasty with other procedures.

CHAPTER 77

Noninvasive and Minimally Invasive Body Contouring

JASON N. POZNER, BARRY E. DiBERNARDO

Weight loss in the United States is a \$30 billion industry that encompasses pharmaceuticals, gyms, diet aids, books, and surgical and nonsurgical interventions. Obesity and weight reduction are global issues; current data show that one third of adults in the United States are obese and another third are overweight. Estimates indicate that these numbers are increasing worldwide. Plastic surgeons have long been involved in fat reduction and body-contouring procedures. According to data from the American Society for Aesthetic Plastic Surgery, liposuction is currently the second most frequently performed aesthetic surgical procedure in the United States, with approximately 283,000 operations performed by core specialists in 2009. This number may be far greater when laser liposuction procedures are factored in, performed by the emerging market of non-core specialists.

Nonsurgical fat reduction is part of the noninvasive body-contouring industry and includes devices for fat reduction, cellulite treatment, and skin tightening. There is some overlap of these devices, because some are marketed for multiple clinical uses. Medical Insight, a California-based aesthetic market research company, forecast that when data are available for 2009, the global market for all body-shaping platforms will be \$361.9 million and that the market will expand by 21% per year, on average, to reach \$752.9 million in 2012.

At this writing there are no devices expressly approved by the FDA for noninvasive fat reduction, although the devices discussed in this chapter are approved for nonsurgical fat removal in many countries outside the United States. We will explore nonsurgical technologies used for fat reduction and examine some of the current devices touted as fat reducers. We will also discuss laser liposuction in depth.

NONINVASIVE FOCUSED ULTRASOUND

Physicians are most familiar with the use of diagnostic ultrasound for imaging; they are less familiar with therapeutic ultrasound, but most have heard of the use of lithotripsy for kidney stones. The actual use of ultrasound in medicine started in 1927, and therapeutic use began in the 1930s with low-energy, unfocused devices. Focused ultrasound was used clinically in the 1950s for treating Parkinson's disease and other brain-related disorders. There was a period of relatively few developments in ultrasound therapy until 1994, when high-intensity focused ultrasound was in-

troduced to treat prostate cancer. Since that time, focused ultrasound has been used to treat many different organs, including, very recently, adipose tissue.

Ultrasound is an interesting medium for fat removal: it can be focused below the skin without causing injury to the skin. This differs from the use of lasers, in which light energy traverses the skin and may be absorbed, scattered, transmitted, or reflected. Ultrasound physics is a bit different from laser physics; a brief overview will help differentiate ultrasound fat removal devices. Ultrasound waves are defined as frequencies higher than the audible spectrum (20 to 20,000 Hz). These are used in medicine and industry, from imaging systems with low energy to focused high energy forms. Terms used to describe ultrasound waves are frequency, sound velocity, and wavelength, which are related by this equation:

$$\text{Velocity} = \text{Wavelength} \times \text{Frequency}$$

The frequencies of the devices may differ, which may have an impact on the treated tissue. The goal of focused ultrasound technology is similar to that of targeted laser therapy: to maximize energy accumulation at the target area to induce a significant biologic reaction without causing collateral damage to the intervening tissues, such as skin and the tissues and structures surrounding and within the target area. The specific goal of ultrasound fat removal devices is to destroy adipose tissue without disruption of nonadipose tissue. The therapeutic devices discussed here are referred to as *high-intensity focused ultrasound* (HIFU) devices; these use high-energy ultrasound waves that are focused on a small spot. The sound intensity (SI) (energy) is measured in Watts/cm². High-intensity ultrasound generally refers to ultrasound with SI higher than 5 W/cm². This type of ultrasound, if used in continuous mode, can cause coagulation necrosis of tissue and is usually used for ultrasonic surgery (such as cancer therapy), as opposed to low-energy physiotherapy ultrasound devices (SI less than 3 W/cm²), which cause nondestructive heating with stimulation or acceleration of physiologic responses to injury.

There are currently two major companies manufacturing noninvasive focused ultrasound devices for body contouring: UltraShape (Tel Aviv, Israel) and LipoSonix (Medicis, Scottsdale, AZ). Other companies have devices in development. There are differences among the devices, and only time and further clinical trials will determine which device is safest and most effective.

UltraShape

Courtesy UltraShape, Yokneam, Israel

The UltraShape device uses nonthermal selective focused ultrasound technology. It received its CE mark in 2005, Canadian approval in 2007, and is currently available in 57 countries. The UltraShape device operates at 200 ± 30 kHz and uses a pulsed ultrasound wave to deliver maximal intensity (580 W/cm^2) and pressure (4.0 MPa) per “burst” of energy. This pulsed ultrasound limits temperature increase and delivers mechanical effects to target and selectively destroy fat cells without harming surrounding structures. UltraShape introduced a new model, Contour I Ver3, in early 2010 with a smaller footprint and higher efficacy.

The original device focused energy at 1.5 cm below the skin surface; the updated device has a multifocal mode. The fat cells within the focal volume are immediately disrupted, and the triglycerides and cellular debris are released into the interstitial space. The triglyceride debris is then cleared through the body’s natural metabolic and physiologic pathways. It is thought that the disrupted adipose tissue is absorbed through the lymphatic system.

UltraShape tracking system

The UltraShape procedure is performed by placing a transducer on the skin surface. No topical anesthetic or tumescent solution is used. A real-time computer tracking and guidance device tracks the ultrasound pulses directed into the adipose tissue. The operator moves the transducer along the skin according to a computer-guided treatment algorithm, and the tracking mechanism ensures complete, uniform treatment and smooth results. There is minimal or no patient discomfort.

Outcomes

The UltraShape device has been used extensively around the world, with more than 150,000 patient treatments performed to date. The safety profile is excellent, with very few adverse events reported. The initial device delivered a 3-second pulse of energy, but recent technologic advances have shortened this to a 1-second pulse, which reduces the overall treatment time with no change in device efficacy. The latest device combines a radiofrequency head into the machine, along with suction to increase the efficacy of the treatment.

More than 20 clinical studies have been published and presented around the world with this device. Circumferential reductions averaged from 2.0 cm in a single treatment to 6.3 cm in a three-treatment series. Patient satisfaction varied from 86% to 93%. Early studies used a single treatment protocol, whereas later studies used multiple treatments. Measurements of blood lipid levels in all studies showed no increase after treatment. An FDA IDE clinical trial was completed in six U.S. sites, including our clinic. Our study involved a 125-patient randomized, double-blind study with a sham control. Patients were treated three times at 2-week intervals, and blood chemistries, MRIs, and photographic evaluations were performed. All safety endpoints were met, with no serious adverse events reported; blood chemistry and lipid profile data were normal. At present, final efficacy data are not yet fully analyzed.

The newest version appears to be more efficacious in early series, but no published studies are available yet.

Results

Case courtesy Mark Lupin, MD

These three patients are shown before and after three treatments with UltraShape. Note the change in abdominal contour.

LipoSonix

LipoSonix is a high-intensity focused ultrasound device for fat reduction. It operates at a frequency in the 2 MHz range. The LipoSonix device is available in Europe and Canada at present and has its CE mark. This device's transducer is placed on the skin, and a scanner similar to a laser scanner delivers a series of pulses into the tissue. The handpiece is moved manually by the operator using a grid pattern, and the process is repeated over the treatment area. The depth of damage is selectable between 1.1 and 1.8 cm. The LipoSonix device has been extensively studied in both animals and humans. The adipose tissue disruption is thought to occur through a thermal mechanism very similar to HIFU treatment of cancers. After destruction of a layer of adipose tissue, the body's natural wound-healing response occurs and clears the thermally damaged tissue through the lymphatic system. As with the UltraShape system, there is no evidence of serum lipid level changes. Clinical studies with this device are ongoing.

According to the manufacturers, the major differences between the UltraShape and LipoSonix devices are that the UltraShape device uses a mechanical effect on the adipose tissue, whereas the LipoSonix system employs a thermal effect. The UltraShape device produces nonthermal stable cavitation to selectively disrupt fat cells without harming surrounding critical structures such as skin, blood vessels, nerves, and connective tissue. The UltraShape device operates at low average intensities to achieve the maximal negative pressure needed to create the purely mechanical effect of cavitation. The nonthermal aspect of the UltraShape device delivers a comfortable treatment with no downtime for the patient. The LipoSonix device relies on the mechanism of thermal necrosis to destroy the subcutaneous tissue. It uses time-averaged high-intensity continuous ultrasound energy delivery to create this thermal effect. The protocol for the UltraShape device is for three treatments 2 weeks apart, whereas the LipoSonix protocol is for one treatment. Initial comparisons suggest that the LipoSonix device may be more efficacious but more painful. Further comparative studies are necessary.

CRYOLIPOLYSIS

Another device that was introduced for nonsurgical fat removal is from Zeltiq Aesthetics (Pleasanton, CA). This noninvasive device is not yet FDA cleared for fat layer removal but does have FDA approval for skin cooling during dermatologic treatment. This means that this device may be used in the United States for nonsurgical fat reduction as an FDA off-label use. The Zeltiq device works on the scientific principle of *cryolipolysis*, by which fat cells are naturally more vulnerable to the effects of cold than surrounding tissues are. This principle is used to selectively destroy and eliminate fat cells without harming the skin. The concept stems from early research

performed by Manstein and Anderson and colleagues of Wellman Center for Photomedicine and Massachusetts General Hospital, a teaching affiliate of Harvard Medical School. Their original theory and research stemmed from observations of frostbite patients, who had fat layer reduction without skin injury. This led to animal studies that confirmed that when fat cells are exposed to controlled cooling, it triggers apoptosis, a process of natural fat cell removal that gradually reduces the thickness of the fat layer. The fat cooling causes crystallization of the fat and fat cell death without injury to adjacent structures. The fat is gradually removed through a macrophage-mediated process similar to that observed through thermally induced fat cell death.

Courtesy Zeltiq, Pleasanton, CA

The device consists of an applicator with cooling panels and mild suction, which is placed directly on the tissue being treated. The fat is cooled over a period of 1 hour per procedure site. No anesthesia is used, and patient discomfort is mild to none. There may be transient erythema and a transient decreased sensitivity to touch following the procedure. The patient can resume normal activities the same day. Fat loss occurs over a 2- to 4-month period. The treatment may be repeated 60 to 90 days later for even greater efficacy.

This device was extensively studied with animal models, followed by human trials. Initial reports of the human trials show very promising results, with 84% of patients showing noticeable improvement. Ultrasound measurements of fat reduction averaged 22.4% for one treatment. Lipid blood levels showed no changes during the postprocedure period. We have had the device in our practices for a few months, and one of the authors (J.N.P.) was treated, with excellent results.

The patient is shown before and 3 months after one Zeltiq treatment of the abdomen.

OTHER NEW TECHNOLOGIES

Other devices that manufacturers claim may cause fat reduction include radiofrequency energy, such as the Alma Accent (Caesarea, Israel) and Thermage (Solta, CA). These devices are used for nonsurgical skin tightening and cellulite treatment. Some reports have suggested that there may be some fat removal when these devices are used at high enough energies. Further research is ongoing.

Another device that has been promoted for nonsurgical fat removal is the Zerona laser (McKinney, TX). This device is a low-level light therapy device (laser 650 nm) that has FDA approval for pain control following liposuction. The claims from the Zerona manufacturer are that an adipose cell has a pore that is opened with exposure to this low-level light. The adipose cell then extrudes its contents, which are absorbed by the body. Initial studies of a predecessor of this device showed no efficacy. Further studies are ongoing.

LASER-ASSISTED LIPOSUCTION

As we have seen, technology has presented several ways of attacking fat. Laser has a unique position in this armamentarium. The fat practice of the future will most likely have three divisions: completely noninvasive for mild cases, minimally invasive for moderate cases, and invasive, reserved for larger patients. Laser-assisted liposuction (LAL) uses a small laser fiber (300 to 1000 microns) delivered through a small cannula of approximately 1 mm. The distinct advance in laser delivery over the past 10 to 15 years is the delivery of laser energy under rather than through the skin. This allows more energy to be placed directly at the target instead of passing through epidermis and dermis, with concomitant cooling mechanisms for protection of the surface from intense heat. The advantages reserved for laser at this point in research are

the proven efficacy in skin tightening, and the safety mechanism has been defined and delineated. Another advantage, because the cannula is small, is the ability to treat scarring, dimpling, and cellulite in the superficial layers without the higher risk of contour irregularity seen with larger cannulas. Disadvantages are the high cost of the equipment, the need for exact temperature measurement, and the potential for burns or blisters without this monitoring. Previous disadvantages were related to time of the procedure; however, as technology progresses, additional wavelengths have been proved to be 40 times more efficient in fat disruption, yet keeping the same small cannula size. This is how technology can advance our treatments in ways mechanical or analog devices could not in the past.

Indications and Contraindications

The indications for LAL take into account analysis of the fat thickness, the physical area in square centimeters to be treated in one setting, and the loss of skin elasticity with increased laxity. Therefore indications include biolysis in patients with mild to moderate thickness of the adipose layer (1 to 6 cm), although larger volumes can be undertaken with the new wavelengths. Patients with mild to moderate skin laxity can now be considered liposuction candidates; in the past, mechanical suction alone would have produced an unpleasant result in these patients. This enhances the age and skin quality range of potential lipoplasty candidates. Those with contour irregularities, scar tissue, or dimpling in the superficial layers of the skin have few other choices for fat removal.

Contraindications include patients with severe skin laxity requiring a surgical solution, patients with a tremendous volume of fat by thickness of area to be treated at one session, and patients with cardiac or similar medical conditions that preclude the use of epinephrine.

Patient Profiles

Good Candidate

A woman in her mid-fifties with moderate fat thickness across 5 cm of the upper and lower abdomen is an example of a prime candidate for LAL. She will have had previous liposuction approximately 10 years ago to the lower abdomen and has residual scar tissue and mild contour irregularity. Her upper abdomen has significant fibrous tissue. Most significant is a mild to moderate skin laxity with loss of elasticity. She is a good candidate because she meets the area and thickness guidelines, and her defects—namely skin laxity and superficial contour defects—are precisely those that can be improved by LAL.

Poor Candidate

A young woman weighing 100 kg (220 pounds) with 10 cm of fat excess in the abdomen as well as excess in the flanks and hips is an example of a poor candidate for this procedure. There is a pannus of skin and fat hanging 4 cm in the lower aspect. She is a poor candidate because of the amount of tissue requiring treatment, and the skin excess, which is far beyond the capabilities of the laser.

Pertinent Anatomy

Superficial and deep treatment planes for laser lipolysis

The pertinent anatomy for LAL treatment is the skin and just below it. The laser initially treats the deep fat. The next zone of treatment is just below the dermis. The third and final step is small cannula suction removal of any debris, oils, and fat cell remnants in the superficial and deep layers.

Pretreatment Assessment

Physical examination is consistent with the patient descriptions noted earlier. Otherwise, general liposuction rules apply.

Patient education focuses primarily on the fact that the skin-tightening effects are variable and that the stimulation of fibroblasts making more collagen and elastin will not be evident until approximately 3 months after the procedure.

Pretreatment Planning

Immediately before the procedure, the areas of fat to be removed are marked. In addition, 5 by 5 cm areas, as measured with a ruler, are marked over the treatment area. This ensures that specific energy levels will be supplied to the deep fat as well as discrete areas for application of heat for stimulation and subsequent tightening of the skin. Incision points (1 to 2 mm) are marked in specific areas to maximize cannula access to the grid, taking into account cannula length and the curvature of the tissue. Treatment becomes more difficult at a distance of more than two or three sectors away from the incision.

If local anesthesia only is used, then the incision points are anesthetized with lidocaine 1%, just forming a wheal in the area; then photographs are taken of the new markings, and oral medications are given. Oral diazepam (Valium) 20 mg and oxycodone/acetaminophen (Percocet), two tablets of 5 mg/325 mg, are used in local cases.

Technique

77-1 Laser
liposuction

Once the patient is positioned on the table and the monitoring equipment has been placed, additional lidocaine 1% with epinephrine 20 to 30 ml is given via a spinal needle through the previously anesthetized incisions to provide additional comfort before the tumescent fluid is administered. The patient is then prepared and draped. Before tumescent fluid is injected, the skin and fat in the area to be treated are pinched and measured for thickness; this information will be used for energy administration guidelines. The surgeon can use the tumescent formula of choice. To ensure proper reaction with the laser, approximately 50 to 100 ml of fluid is given per 5 by 5 cm sector. The next step is the first laser application in the deep tissue. From the previous thickness measurement, 1000 to 2000 Joules of energy are given per centimeter of pinched thickness. Therefore if 3 cm was determined, the deep energy level would be 3000 Joules for normal soft adipose tissue and up to 6000 Joules of energy in thick fibrous or scar tissue. This amount of energy is given to all deep sectors first. The wavelength used for this layer is currently 1440 nm, combined with 1064 nm. In this instance, 1440 has a higher affinity for the fat tissue by approximately 40 times. The mechanism is a higher absorption in fatty tissue, translating to a more intense photomechanical effect. The power density concentrated at the tip of the canula creates pressure-filled microbubbles that eventually collapse, creating both a mechanical as well as a thermal disruption on the adipocyte cell wall.

Next, the laser settings are changed to 1320 nm and 1064 nm; hence the 1320 wavelength has a high absorption coefficient for water, thus enhancing the dermal heating component.

Temperature Monitoring

Courtesy Cynosure, Westford, MA

Safety requires precise temperature monitoring for the skin-tightening phase. The basis of the temperature goals and safety parameters were published, establishing the 42° C (107.6° F) temperature goal in this layer. Too little heat will not achieve the clinical goals; too much heat will risk blistering or burning with subsequent scars. Currently there are three methods for monitoring temperature:

1. A handheld, laser-guided thermometer (least accurate)
2. A thermistor placed at the tip of the operating cannula
3. An overhead infrared thermal camera

The latter two have the capability to be tied into the laser computer to stop the laser from firing as goal temperatures are achieved. These systems, although highly accurate and safe, come at a significantly higher cost.

Once laser applications have been completed in all sectors, the last phase is to remove fat oils, cell fragments and other debris with small liposuction cannulas. Wounds are either closed or left open in the dependent positions. Foam and a compression garment are placed, and the rest of the postoperative care is similar to that for other liposuction procedures.

Posttreatment Care

Although posttreatment care is similar to that in other liposuction protocols, laser treatment patients can usually return to sedentary work in 2 to 3 days. Although the laser and the 1064 nm wavelength help to coagulate small vessels, which results in less bruising, swelling is still a factor. Therefore routine compression, massage, and limitation of activity are required.

Problems and Complications

As with any liposuction, associated complications are similar to the laser procedure. Complications can occur in three categories: systemic, local, and device based. The box lists the complications per category.

Potential Complications

Systemic

Infection
Hemorrhage
Hypovolemia
Third space fluid shift
Deep vein thrombosis
Fat embolism
Pulmonary embolism
Abdominal perforation
Necrotizing fasciitis
Lidocaine toxicity
Epinephrine toxicity
Visual loss (idiopathic intracranial hypertension)
Death

Local

Undercorrection (insufficient fat removal)
Overcorrection (excess fat removal)
Contour irregularities
Unevenness
Seroma
Hematoma
Incision scarring
Cutaneous slough
Hyperpigmentation
Poor skin tone

Device-Based

End hits
Blisters
Burns
Blowholes
Prolonged edema
Heat/pressure problems
Neurapraxia
Permanent nerve damage
Hyperlipidemia
Contour irregularity
Insufficient effect

Outcomes

Patient outcomes are very closely related to the efforts by the surgeon to apply appropriate energy in the deep layers, obtaining a temperature as close as possible to the 42° C (107.6° F) goal and performing a thorough suction at the end. These procedures require time and work, but the results should be worth the efforts. Ten consecutive patients were presented at an American Society of Plastic Surgeons meeting; there was high patient satisfaction, safety, and a minimum of complications. One patient was noted to have had a temporary postinflammatory hyperpigmentation. In the initial few months of use of the device, some blisters and burns were reported, but these occurred before we gained experience with the technique and with proper temperature monitoring.

Results

This 29-year-old woman is shown before and 2 months after a SmartLipo MultiPlex (Cynosure) treatment on the neck, with a total of 16,198 Joules. Note the fat removal and skin tightening.

This 55-year-old woman is shown before and 2 months after a SmartLipo MultiPlex treatment on the arms, with a total of 31,684 Joules. Regular liposuction would not have been able to provide this tissue contraction.

This 50-year-old patient is shown before and 3 months after SmartLipo treatment on the neck. Note the skin contraction.

This 47-year-old patient is shown before and 1 month after a SmartLipo treatment on the lower abdomen and flanks. She has excellent skin contraction.

Concluding Thoughts

Nonsurgical fat removal is still in its infancy. The nonsurgical devices in use today differ in their mode of operation—cryolipolysis versus ultrasound—and differ in their efficacy and the level of pain the patient experiences. Future technology may make it possible to visualize and remove specific fat deposits with greater efficacy and minimal pain. We have proved that laser liposuction destroys fat and tightens skin; however, the biologic mechanism of tightening needs to be elucidated. We need further study to ascertain the time and temperature levels that lead to new collagen formation. We believe the questions will be answered in the ensuing years.

Clinical Caveats

Proper patient selection is critical.

The safety and efficacy of the laser device selected must be researched thoroughly.

There are no shortcuts to proper energy application.

The face and neck have much thinner skin and require additional caution.

Annotated Bibliography

DiBernardo BE, Reyes J. Evaluation of skin tightening after laser-assisted liposuction: preliminary results. *Aesthet Surg J* 29:400-407, 2009.

This paper was the preliminary report and study designed to quantitatively assess clinical skin tightening and skin shrinkage after laser-assisted liposuction.

CHAPTER 78

Liposuction:

Basic Techniques and Safety Considerations

JORDAN P. FARKAS, PHILLIP J. STEPHAN,
JEFFREY M. KENKEL

Suction-assisted lipectomy, or lipoplasty, more commonly referred to as liposuction, originally introduced by Illouz in the early 1980s, continues to be one of the most popular body-contouring and overall treatment modalities offered in aesthetic surgery today. According to the American Society for Aesthetic Plastic Surgery, in 2009 more than 283,000 liposuction procedures were performed in the United States, which placed it second among all types of invasive cosmetic procedures. With greater understanding of the biochemical and physiologic properties of liposuction as well as biomedical technologic advancements, suction-assisted lipoplasty has undergone a tremendous evolution, leading to overall improvements in technique, patient safety, and outcomes. Over the past two decades, it has grown from a procedure that facilitates small or spot reductions to one that has become an almost irreplaceable tool in aesthetic surgical procedures of the neck, breast, and circumferential body contouring. Liposuction has become a useful adjunct to other areas of plastic surgery, including breast reconstruction and postoperative contouring in upper and lower extremity reconstruction. Important innovations and modifications to standard suction-assisted lipoplasty (SAL) involving the introduction and/or refinement of wetting solutions and cannulas have assisted in refining the procedure, and other novel technologies have been introduced, including ultrasound-assisted liposuction (UAL), power-assisted liposuction (PAL), vaser-assisted liposuction (VAL), and laser-assisted liposuction (LAL). There has been a strong movement toward defining appropriate safety guidelines for liposuction and other body-contouring procedures, with a focus on deep venous thrombosis prophylaxis and fluid resuscitation.

Even with these refinements, liposuction, as with all invasive procedures, is still not without risk. Aesthetic body contouring with liposuction requires a comprehensive knowledge of the anatomic, biochemical, and physiological components of the various modalities and their limitations and indications to perform the procedure in a safe, controlled manner. Using a coordinated approach along with a thorough understanding, liposuction can be performed safely with relatively predictable results and outcomes.

Pertinent Anatomy

Anatomy texts divide subcutaneous fat throughout the body into superficial and deep layers or compartments separated by Scarpa's fascia, or the superficial fascial equivalent. However, for the purposes of liposuction and body contouring, subcutaneous fat is arbitrarily divided into three layers: superficial, intermediate, and deep.

The importance of this distinction is that the superficial layer is rarely violated. If this layer is treated, there is a significantly increase risk of vascular compromise and/or contour irregularities. The relative consistency and thickness of each of these separate layers vary in different anatomic areas. For example, the fat of the back has a more fibrous, compact superficial and intermediate layer with an underlying loose, areolar layer. This contrasts with the fat of the inner thigh, which is not as fibrous and is less compact. This information is crucial for an aesthetic surgeon to perform safe and appropriate suctioning of the targeted area and to minimize potential contour irregularities and skin necrosis.

In this chapter we will discuss the variation in fat consistency and depth as it relates to safe suctioning techniques, and which modalities may be preferred for the most effective treatment.

ZONES OF ADHERENCE

Previously described anatomic zones of adherence (see Chapter 77), which are present in both men and women, should be identified and marked during the preoperative consultation. These are areas of relatively dense fibrous attachments to the underlying deep fascia that help define the natural shape and curve of the body. There are sex-specific variations with respect to each of these zones. It is important to recognize these zones, because they are high-risk areas for contour irregularities after surgical intervention if not properly respected.

However, these zones of adherence are not areas to avoid in all cases, and on occasion they help to guide the surgeon in establishing contour goals. Regardless of the type of liposuction selected, it is helpful to consider the treatment area in terms of the three surgical layers. These arbitrary layers delineate areas of safety during liposuction. The most common area treated is the intermediate layer, and often the deep layer. Treatment of these layers allows uniform reduction without risk of injury to the subdermal plexus and skin.

Indications and Contraindications

Liposuction patients often present with a variety of expectations, concerns, and/or complaints. To achieve optimal contour with liposuction appropriate patient selection is imperative. As a general rule, liposuction is performed in healthy patients who maintain realistic goals and expectations. Studies have shown that patients who undergo appropriate long-term lifestyle changes will in fact achieve the highest level of postoperative satisfaction from their liposuction-assisted body-contouring procedure. Broughton et al found that patients who were committed to positive lifestyle changes involving a healthy diet and regular exercise or who were already practicing a healthy lifestyle that continued postoperatively scored the best on self-assessment and satisfaction evaluations after liposuction. To achieve and maintain optimal results, a body-contouring patient must satisfy four key elements: (1) lifestyle change, (2) regular exercise, (3) a well-balanced diet, and (4) body contouring.

Appropriate candidates for liposuction are not morbidly obese, are at a stable weight, and have incorporated the above lifestyle changes into their preoperative regimen. It is preferable for patients to commit to the necessary changes in diet, exercise, and lifestyle modification before undergoing surgery. It is the responsibility of the surgeon to address all concerns, expectations, and goals with the patient before the procedure to establish realistic expectations of the procedure. Preoperative consultation with a dietician may prove beneficial for long-term patient satisfaction. Liposuction

is contraindicated in patients who are pregnant or in poor general medical health. Patients with morbid obesity, cardiopulmonary disease, body image perception issues, unrealistic expectations, wound-healing difficulties, or with extensive or poorly located scars should be excluded from consideration for liposuction.

Patient Profiles

There are three types of lipodystrophy and skin redundancy.

TYPE I: LOCALIZED LIPODYSTROPHY Type I patients tend to be younger, with normal skin tone and minimal skin irregularities.

This 21-year-old woman is in good health but has mild lipodystrophy in her abdomen, hips, and thighs.

This 20-year-old man is an extremely active cyclist who has refractory lipodystrophy and mild skin redundancy in his lower abdomen.

TYPE II: GENERALIZED LIPODYSTROPHY Type II patients tend to have slightly diminished skin tone with some skin irregularities and circumferential lipodystrophy throughout their trunk and extremities.

This 33-year-old woman has diffuse lipodystrophy in her abdomen, hips, and thighs that has been resistant to diet and exercise.

This 27-year-old woman has diffuse lipodystrophy and some mild skin laxity in her abdomen.

TYPE III: SKIN REDUNDANCY AND LIPODYSTROPHY Type III patients have significant skin redundancy that would be more amenable to excisional surgical techniques to improve shape and contour. If necessary, liposuction may be performed as an adjunct procedure to achieve an optimal result.

This 59-year-old woman is interested in truncal rejuvenation. She is unhappy with the central lipodystrophy that has recurred after menopause. She will benefit from liposuction to her thighs and back as well as circumferential abdominoplasty.

This 47-year-old woman has lost more than 45 kg (100 pounds) and desires improvement of her central trunk. She has minimal lipodystrophy and will benefit from circumferential abdominoplasty.

Preoperative Assessment

Initial Evaluation

During this initial interaction, it is imperative that the plastic surgeon be able to assess the patients' goals from surgery and be able to determine whether the patient has realistic expectations regarding outcome and postoperative body image. It may be useful to have the patient prioritize the body regions that he or she is most concerned with, focusing on specific complaints within these areas. A detailed medical history should be obtained, including any allergies, and whether the patient uses tobacco. Especially important data include a history of diabetes, massive weight loss, previous surgery, previous liposuction, and a full detailed list of medications and supplements. Any concerns about a patient's medical suitability to undergo anesthesia and/or an operative procedure should result in referral for preoperative clearance by an internist or a cardiologist. Patients should be asked specifically about herbal and over-the-counter medications, because they frequently fail to mention these. Nonessential medications should be discontinued at least 3 weeks before surgery. In selected patients, a preoperative evaluation by a primary care doctor, internist, or cardiologist may be warranted. This typically includes anyone with a significant medical history or patients older than 50 years of age.

It is often prudent to notify the consulting physician of expected operative times and the amount of expected aspirate and infiltrate. Often our medical colleagues view liposuction as a very benign operation with minimal operative time and morbidity, when in fact a large-volume liposuction procedure can involve significant fluid shifts and time under general anesthesia. Massive-weight-loss patients should undergo the same preoperative evaluation and clearance for liposuction as they would for any excisional type of body-contouring procedure (including nutrition, hemoglobin and iron assays, B₁₂, and so on). Herbal remedies and supplements are not regulated by the FDA and thus may place the patient at potential risk of untoward complications, including bleeding or hypercoagulability; these products should be avoided in the perioperative period. Avoiding aspirin, NSAIDs, and hormonal therapy can help prevent such complications as well. We advise patients to discontinue use of all NSAIDs, aspirin products, fish oil, and supplements 3 weeks before surgery. Of course, if there is a medical indication and necessity for these drugs, consultation with the primary physician or appropriate specialist should be completed before the medical therapy is discontinued. A frank discussion of the risk of oral contraceptives and estrogens is held with the female patients, regardless of the magnitude of the procedure. We strongly recommend that these medications be discontinued 1 month before the procedure.

Physical Examination

A detailed physical examination is performed at the first visit. Specific attention to prior scars, the presence or absence of hernias, evidence of venous insufficiency, and any preexisting asymmetry or contour irregularity should be discussed and noted in the chart. At the initial and subsequent visits, the patient's height and weight are measured and BMI calculated. This is of paramount importance for safety as well as to track long-term trends during follow-up. For liposuction candidates, six key elements are documented:

1. Evaluation of areas of lipodystrophy and contour deformities
2. Skin tone and quality
3. Asymmetries
4. Dimpling and cellulite
5. Myofascial support
6. Zones of adherence

The physical examination is best performed with the patient in front of a full-length mirror. This allows an open dialog between the patient and physician during the exam so that the patient's concerns can be addressed, and previously unrecognized problem areas can be assessed and discussed. Any areas of cellulite should be pointed out to the patient, and the expected outcome in these areas should be discussed. At the initial evaluation, high-quality medical photographs should be obtained, with anterior, posterior, and lateral views as well as anterior and posterior oblique views. These images will allow documentation of results and aid objective evaluation of outcomes by both the patient and physician. Professional medical photography can be a very useful tool for accurate and consistent preoperative and postoperative documentation.

With the patient facing away from the physician, the spine is assessed for abnormal curvature. This is more easily appreciated with the patient bending at the waist with the hands held forward and together in front of the body. This is often the first clue that significant asymmetries may exist. Skin tone and quality are assessed using the pinch test. The patient is examined from the anterior direction, both lateral directions, and finally in the supine position.

While the patient is in a supine position with the head elevated, abdominal integrity is assessed. This is helpful for detecting hernias or myofascial diastases. Findings may be difficult to interpret in larger individuals or in patients with multiple scars. An ultrasound examination or CT scan may further clarify findings in this region and prevent intraabdominal injury. During the initial consultation, when the patient is in front of the mirror, it is important to point out potential problem areas that may cause less than optimal results so the patient can visualize and appreciate these areas.

A follow-up visit is typically scheduled 2 to 3 weeks after the initial consultation. During this visit, computer images are reviewed, which allows the patient to establish realistic expectations. These objective images portray the advantages, disadvantages, and limitations of body-contouring surgery. The patient should understand that imaging is for educational purposes only and is *not* a guarantee of the final result. During the second visit, the patient can ask any remaining questions, such as concerns about recovery time, pain control, bruising, and postoperative changes. Such discussions help to strengthen the patient's confidence in the procedure and decrease the likelihood of any uncertainties or surprises in the perioperative period.

Patient Education and Informed Consent

Patient education is stressed throughout the course of the initial evaluation, physical examination, and follow-up visit so the patient has sufficient information about the procedure, postoperative course, and long-term results to make a truly informed decision. The patient and physician should discuss the procedure itself, alternative treatments, and complications and risks. The risks for liposuction include, but are not limited to, bleeding, infection, pain, thermal injury, seroma, dyspigmentation, paresthesias, contour irregularities, and dysesthesias. The informed consent process is necessary to protect the patient and surgeon. The patient coordinator explains financial obligations (including those for further surgeries if required).

Preoperative Planning

Markings

Preoperative marking is essential to perform successful liposuction. Patients should be marked in the standing position and in front of a mirror, if possible. This allows the patient to contribute to the process and further confirms exactly what will be addressed during the procedure. The four-position stance is preferred. Areas to be suctioned are marked with a circle; zones of adherence and areas to avoid are marked with hash marks. Asymmetries, cellulite, and dimpling are marked for their respective treatment. When complete, the marks are once again reviewed with the patient to ensure that all areas of concern are addressed.

Access incisions are also marked at this setting. With liposuction, it is beneficial to choose access points that can treat multiple areas. Incisions should also allow each area to be treated from different directions for optimal contouring.

Incisions should be no longer than 3 to 4 mm in length and placed in well-concealed areas. The surgeon should not hesitate in placing additional incisions if access is insufficient with the existing markings.

The preoperative markings and preferred placement of access incisions based on areas to be suctioned are shown.

Cosmetically, it is preferable to stagger incisions asymmetrically to camouflage their appearance.

Anesthesia Technique/Location of Operation

The choice of anesthesia technique for liposuction varies based on multiple factors: operating surgeon preference, anesthesiologist preference, amount of expected lipoaspirate, length and extent of procedure, patient positioning, and overall health of the patient. Local anesthesia, various forms of sedation (mild, moderate, heavy) and general anesthesia are described in the literature. No single anesthesia technique has proved superior over another. However, the practice advisory on liposuction does recommend avoiding epidural and spinal anesthesia in office-based settings because of potential hypotension and volume overload issues.

Small-volume liposuction cases can be performed with a local anesthetic, with or without mild sedation. Complex, large-volume liposuction and combined cases should be performed with the patient under general anesthesia. We perform the majority of cases with a general anesthetic. Deep-sedation cases and general anesthesia procedures are performed under the supervision of board-certified anesthesiologists in licensed surgery centers or hospitals. All cases in which the patient is in a prone position are performed with general endotracheal anesthesia for airway control.

The operative location should be determined after careful patient evaluation, assessment of the complexity of the procedure required, and appropriate review of medical comorbidities. The anticipated postoperative course and the need for possible overnight observation both factor into the choice among inpatient, observation, or outpatient hospital settings.

Special importance should be given to medical comorbidities, such as obstructive sleep apnea. The current American Society of Anesthesiology recommendations are that for patients with signs or symptoms that suggest moderate to severe obstructive sleep apnea, surgery be performed in a hospital setting with extended recovery and observation to prevent postoperative respiratory complications. It is recommended that liposuction procedures, whether inpatient or outpatient, be performed in an accredited facility equipped to manage any postoperative insult or sequela.

It is useful to have the circulating nurse maintain an accurate liposuction data sheet to facilitate consistent and accurate communication among the surgeon, the anesthesiologist, and the operating room team.

Patient Positioning

The patient is placed in a forced-air warming blanket 30 to 60 minutes before the procedure. Pedal or calf sequential compression devices are also applied in the holding area at this time.

Prone/Supine

Once the patient is in the operating room, the compression devices are reapplied and the patient is placed under general anesthesia. We prefer to position the patient prone. A soft hip roll is placed beneath the iliac crests to elevate the treatment areas off the bed, and either pillows or longitudinal rolls are used to support the upper chest. The breasts should be placed medially and the nipples protected.

The patient's arms are extended on padded arm boards at less than 90 degrees from the long axis of the table. The patient's face must be appropriately padded, the cervical spine is placed in a neutral position, and the eyes are protected. Patients in the prone position are subjected to pressure changes over the forehead, malar areas, iliac crest, and bony prominences of the arms and legs. Special attention also needs to be given to the genitals. In the prone position, up to 70% of the contouring can be performed and may include liposuction of the arms, back, hips/flanks, and lateral, posterior, and medial thighs.

With the patient transferred to the supine position, the remainder of the trunk and extremities can be addressed. This may include treatment of the arms, abdomen, anterior medial thighs, and knees. This position does not have significant effects on the cardiopulmonary system. Brachial plexus injuries can occur if the arm is abducted at greater than a 90-degree angle. The hips and knees should be flexed at approximately 30 degrees with a pillow. Pressure points in the supine position include the occiput, scapula, posterior iliac crest, sacrum, and heels.

Wetting Solutions and Perioperative Fluid Management

At one time, liposuction was performed without the use of any infiltrated wetting solution, which resulted in blood loss of up to 45% of aspirate in some areas. Liposuction has since evolved to include the addition of infiltrating subcutaneous wetting solutions before suctioning to provide hydrodissection, improve hemostasis, and potentially provide some perioperative analgesia.

The current options for wetting solutions are dry, wet, superwet, and tumescent. The dry technique uses no wetting solution and has few if any indications in liposuction. The wet technique involves preinfiltrating 200 to 300 ml of solution per region to be treated, regardless of the anticipated amount to be aspirated. The superwet technique employs infiltration of 1 ml of solution per estimated cubic centimeter of expected aspirate. Finally, the tumescent infiltration popularized by Klein involves extensive infiltration of wetting solution that creates significant tissue turgor and results in total infiltration of 3 to 4 ml of wetting solution per cubic centimeter aspirated. Regardless of the technique used, the infiltrate should be allowed to set for 7 minutes and no longer than 30 minutes before suctioning is initiated because of the estimated onset of action of the anesthetic and vasopressor agents in the solution. Negligible blood loss, less than 1% of the lipoaspirate, is observed when using either the superwet or tumescent technique.

Estimated Blood Loss With Different Liposuction Techniques

Technique	Estimated Blood Loss as a Percentage of Volume Aspirated
Dry	20-45
Wet	4-30
Superwet	1%
Tumescent	1%

Techniques of Liposuction and Infiltrates

Technique	Infiltrate	Volume Aspirate
Dry	No infiltrate	To treatment endpoint
Wet	200-300 ml/area	To treatment endpoint
Superwet	1 ml infiltrate:1 cc aspirate	1 cc aspirate/infiltrate (treatment endpoints)
Tumescent	Infiltrate to skin turgor	2-3 cc aspirate/ml

Some authors have popularized different variations of these solutions, but all of the formulations include some variant of fluid (normal saline solution or Ringer’s lactate solution), epinephrine, and lidocaine. Bupivacaine (Marcaine) should be avoided because of its potential cardiac effects and duration of action; it has yet to be proved clinically as a suitable anesthetic in wetting solutions. The most common solution mixtures are shown in the table on p. 2761.

Lidocaine

Lidocaine is the local anesthetic that most surgeons choose to include in the wetting solution. It has been reported to provide analgesia for up to 18 hours postoperatively when injected in dilute concentrations into the subcutaneous space. The recommended maximum dose of lidocaine with epinephrine is 7 mg/kg, according to the *Physicians’ Desk Reference*; however, numerous studies have documented the safety of lidocaine in concentrations greater than 35 mg/kg and as high as 55 mg/kg in large-volume cases. These higher doses have proved to yield peak plasma levels below the toxic range. It is thought that the dilute nature of lidocaine and slow infiltration delay absorption and reduce the peak plasma concentration. Additionally, the inclusion of epinephrine, the relative avascularity of fatty tissue, and the high lipid solubility of lidocaine all seem to contribute to the delayed absorption. There are many variables to consider when incorporating lidocaine into a wetting solution. First, the lidocaine absorption rate is extremely variable and dependent on multiple factors, including the activity of the cytochrome P450 system, drug interactions, fluids, and concentrations of the drug administered. Medications that tend to increase lidocaine levels include oral contraceptives, beta-blockers, and tricyclic antidepressants.

Most Common Wetting Solution Mixtures

Ingredient	Amount (ml)
Klein's Formula	
Normal saline solution	1000
1% lidocaine	50
1:1000 epinephrine	1
8.4% sodium bicarbonate	12.5
Hunstad's Formula	
Ringer's lactate solution	1000 at 38° to 40° C
1% lidocaine	50
1:1000 epinephrine	1
Fodor's Formula	
Ringer's lactate solution	1000
Aspirates <2000 cc 1:500 epinephrine	1
Aspirates 2000 to 4000 cc 1:1000 epinephrine	1
Aspirates >4000 cc 1:1500 epinephrine	1
UT Southwestern Formula	
Ringer's lactate solution	1000 at 21° C
Aspirates <5000 cc 1% lidocaine	30
Aspirates >5000 cc 1% lidocaine	15
1:1000 epinephrine	1

One area that is still under investigation is the importance of *monoethylglycinexylidide* (MEGX). MEGX is an active metabolite of lidocaine that is less protein bound and thus pharmacologically more active. It has been reported to be up to 83% active, meaning that it will contribute to the overall activity of lidocaine and ultimately its potential toxic effects. It has been demonstrated that the peak levels of the metabolite MEGX occur within 8 to 32 hours after initial infiltration. The peak systemic level was greater than initially thought, but still below the level of toxicity. Based on a recent study, this may increase the concentration of active metabolite up to 1 mg/ml.

At our institution, a concern about the volume of infiltrated lidocaine and possible toxicity levels led to a modification in the mixture of wetting solution in large-volume liposuction cases. In cases with aspirate greater than 5000 cc, the initial five bags of solution are mixed in a standard UT Southwestern protocol (see the table above). After 5 L of infiltration, the remaining bags of infiltrate contain lidocaine 1% plain at half the volume (15 ml).

However, a recent study at our institution showed that tissue levels of lidocaine beyond 8 hours postoperatively are subtherapeutic. A well-designed study by Hatef et al prospectively randomized liposuction patients to receive preoperative subcutaneous infiltration of 10, 20, or 30 mg/kg of lidocaine wetting solution before the pro-

cedure, observing patients' intraoperative anesthesia requirement, postoperative pain, and need for postoperative analgesia. Surprisingly, no significant difference was found among any of the three groups. We have since eliminated lidocaine in our wetting solutions and have noted no difference in our patients' postoperative recovery or pain levels.

Further investigation on the use of bupivacaine in low doses may provide another alternative for postoperative analgesia. A recent article by Failey et al demonstrated no significant difference in the incidence of adverse events or postoperative length of stay for patients who underwent liposuction procedures in which bupivacaine was administered, compared with other wetting solutions.

Epinephrine

The importance of epinephrine in subcutaneous infiltrates has been well recognized. In addition to its vasoconstrictive effect, it also decreases the rate of vascular absorption of lidocaine, potentiating the local anesthetic effect. Epinephrine toxicity can result in tachycardia, hypertension, and arrhythmias. Many investigators have studied the doses of epinephrine in wetting solutions. It has been reported to have an upper safety limit of 15 mg per surgical procedure. Regardless, it is known that epinephrine, even in small concentrations, may still have a profound effect on the cardiovascular system.

In a study to evaluate the hemodynamic effects of epinephrine during liposuction surgery, we found a linear correlation between the epinephrine concentration and cardiac index. Although the doses of epinephrine are low and its half-life is less than 2 minutes, peak concentrations do not occur until about 5 hours after infiltration. In larger-volume cases, we recommend that infiltration be staged, decreasing the peak effect of epinephrine and its subsequent effect on the cardiovascular system. Regardless, a thorough preoperative patient evaluation with special attention to the presence of cardiovascular disease should be performed to avoid the untoward effects associated with epinephrine infiltration in some patients.

Although rarely used, halothane may sensitize the heart to catecholamines, resulting in ventricular arrhythmias. *Despite the protective effect of lidocaine against arrhythmias, halothane should not be used during liposuction procedures.*

Regardless of the technique used, the infiltrate should be allowed to set for a minimum of 7 minutes and no longer than 30 minutes before suctioning because of the estimated onset of action of the anesthetic and the vasopressor in the solution.

Current Recommendations for Perioperative Fluid Management

Guidelines were developed by Rohrich et al in 1998 (and updated in 2006) after a thorough review of 100 consecutive procedures using the superwet technique (see the box below). Perioperative fluid management during liposuction procedures requires attention to maintenance intravenous fluids, third-space losses, wetting solution infiltration, and volume of lipoaspirate. We tend to diminish any preexisting fluid deficits, because our current preoperative guidelines allow patients to consume clear liquids up to 2 hours before surgery. Liposuction in our hands is considered a moderate surgical stress; therefore 3 to 5 mg/kg/hr of crystalloid solution is adequate volume for maintenance replacement and third-space losses. Additional fluid may be given during procedures in which the lipoaspirate amount is more than 5 L. A ratio of 0.25 ml of crystalloid solution for each aspirated cubic centimeter over 5 L is used.

Fluid Resuscitation

Body-contouring procedures can result in significant fluid shifts and intravascular volume changes for the patient. The operating surgeon should maintain a dialog with the anesthesia provider so that patients receive adequate replacement volume and proper fluid resuscitation intraoperatively. Awareness of four key elements will guide the intraoperative fluid management of liposuction patients: intravenous fluid maintenance (body weight dependent), third-space losses, the volume of the wetting solution infiltrated, and total lipoaspirate volume. Large-volume liposuction patients can present an especially difficult challenge for fluid resuscitation. We routinely place Foley catheters in patients undergoing large-volume aspiration to assist us in resuscitation.

Fluid Management

1. Replace losses from preoperative oral intake loss as needed.
2. Maintain fluid throughout the procedure and manage it based on vital signs and urine output.
3. Employ the superwet infiltration technique.
4. Administer crystalloid replacements, 0.25 ml for each cubic centimeter of lipoaspirate over 5 L.

These recommendations serve as a guideline for fluid management of these complicated patients and are not meant to replace sound clinical judgment based on specific patient needs.

Treatment Options

Once having determined that lipoplasty would be the best treatment option to accomplish the planned aesthetic goals, the surgeon focuses on selecting the appropriate modality. Factors that influence the selection of a particular type of treatment include surgeon preference, target area, expected volume of aspirate, and history of previous liposuction. Current options include traditional liposuction, as popularized by Illouz, which today includes SAL, PAL, UAL, VAL, LAL. Traditional SAL remains the most common and popular modality for lipoplasty among plastic surgeons.

SAL is a two-stage technique in which the site is infiltrated with a predetermined wetting solution and then evacuated after allowing time for the epinephrine to take effect. The advantages of this technique include the ease of use, wide variety of cannulas, availability of malleable cannulas, and decades of experience and results. The disadvantages of SAL include its being more difficult to use in fibrous areas and typically requiring more effort to perform than other liposuction modalities.

PAL electric handpiece

Complete PAL system

PAL uses an externally powered cannula, variable in size and flexible, and oscillates in a 2 mm reciprocating motion at rates of 4000 to 6000 cycles per minute. Advocates of PAL contend that it is best used for large volumes, fibrous areas, and revision liposuction. Because the PAL cannula breaks up fibrous fat much more readily, the procedure is significantly faster and less labor intensive for the surgeon than traditional SAL. Suction is still a major component of PAL, and most units are compatible with standard aspiration equipment. Both the power source and the suction are attached to the proximal end of the handpiece. If the surgeon prefers, syringe suction is a useful adjunct and can be used with an adapter. As with SAL, many probe tip configurations and diameters are available. PAL systems have multiple power settings, especially the computer-controlled systems that can be programmed.

Some of the disadvantages of earlier PAL systems, which ran on compressed air, included significant noise generation and the mechanical vibration experienced by the operating surgeon. However, these modalities now run on electrical power sources, decreasing the degree of noise and vibration. We find that the PAL system is bulky and somewhat cumbersome, making fine contour changes more difficult.

UAL applies ultrasonic energy to break down fat and facilitate suction-assisted removal. Its mechanism of action is also primarily mechanical in nature, but cavitation and even thermal effects are purported to occur. With this technique, fat is emul-

sified, which allows removal through traditional liposuction cannulas. UAL comprises three stages: infiltration, emulsification, and evacuation and contouring.

To help protect the skin from thermal injury, some operators limit their application of energy and bathe the access site with saline solution. A towel should cover the region behind the access site to prevent direct contact of the probe with the skin during excursion. As with the other technologies, a variety of probe tip configurations and lengths are available, including hollow and solid devices.

For UAL, we begin at a depth of approximately 1 to 2 cm, depending on the body area. The plane is treated uniformly, beginning at one side of the area and moving in a radial fashion to the contralateral side. We continue in this manner until the endpoint is reached. Then we move to a deeper plane. Most treatment sites will have a minimum of two planes and sometimes three. When the last plane is completed, evacuation begins in the deeper plane to remove the emulsified fat. Next, we begin final contouring, if necessary. We are fairly conservative in our choice of cannulas. Smaller cannulas are less efficient at evacuating fat but decrease the likelihood of contour irregularities. It is important that UAL endpoints be respected to avoid overzealous resection of fat. The advantages of UAL include less surgeon fatigue as well as improved results in fibrous areas and in secondary procedures. We have found that our revision rate over the years has dropped from just under 10% to less than 3%. We think that UAL allows a more uniform and homogenous treatment of the fatty layers. The disadvantages have been reported to include the need for larger incisions, longer operative times, and the possibility of thermal injury. Although there is a potential for thermal injury, this does not typically occur with the application times we use today. UAL requires a superwet environment and cannot be performed without a wetting solution. Finally, UAL requires continuous movement to prevent excessive exposure of the tissues to heat.

VAL employs a newer-generation ultrasound-assisted liposuction device that incorporates less energy with more efficient solid probes. The probes come in an array of sizes and grooving, and their selection depends on the tissues in which they will be used. The system uses less energy, decreasing its thermal component to the tissues.

Left, Smartlipo system; center, ThermoView; right, ThermoGuide probe

LAL has been at the forefront of marketing efforts for the past several years. The treatment involves insertion of a laser fiber through a small skin incision. Depending on the manufacturer, the fiber may either be housed within a cannula or stand alone. There are several commercially available lasers on the market under different product names. The most common available wavelengths in the United States are 924/975 nm, 1064 nm, 1319/1320 nm, and 1450 nm.

Most companies and physicians using these LAL devices employ a four-stage technique: infiltration, application of energy to the subcutaneous tissues, evacuation, and subdermal skin stimulation. The laser fiber purportedly acts to disrupt fat cell membranes and emulsify fat. Evacuation then commences through traditional liposuction cannulas. For smaller regions, such as the neck, some manufacturers suggest skipping the evacuation phase, allowing the body to absorb the liquefied contents.

These devices are being heavily marketed for their purported skin-tightening effects. The belief is that the heating of the subdermal tissue may in fact be the contributing factor for LAL's possible skin-tightening effect. No large prospective trials have been undertaken to examine the benefits of LAL over existing technologies, so unfortunately, these reports remain completely anecdotal. DiBernardo and Reyes evaluated skin tightening and skin shrinkage after treatment with a 1064/1320 nm laser in the abdomens of five patients and found a 26% improvement in skin elasticity and an average reduction in area of 17%.

A randomized, double-blind, controlled study by Prado et al showed no difference in the outcomes of LAL compared with those of traditional SAL. In that study, each patient served as his or her own control. Factors evaluated included cosmetic result, postoperative pain, length of operation, lipocrit, and free fatty acids. Besides the lack of difference in the cosmetic outcome of LAL versus SAL, the authors reported a longer operative time with LAL, less early postoperative pain with LAL, and elevated free fatty acids/triglycerides in the laser-treated lipoaspirate. Regardless of its efficacy in tightening skin, we must recognize that there is a fine line between dermal contraction and full-thickness injury when applying heat to the subdermis.

Surgical Endpoints

The surgical endpoints for UAL are different from those of SAL and PAL; these have been divided into primary and secondary endpoints. In UAL, the most important endpoint is reached when one encounters a loss of tissue resistance, which is appreciated through the treatment hand as well as the nondominant guiding hand. Additionally, the aspirate may become more blood tinged, indicating adequate emulsification of the treatment site. Experience helps dictate energy application times in particular regions of the body. Secondary endpoints for UAL include site-specific treatment time and the volume to allow for comparison of size and symmetry of treatment on either side. Contour should not be judged during emulsification or the evacuation phase. Once evacuation is complete, the contour may be assessed. Alternatively, treatment with SAL or PAL uses final contour and symmetrical pinch test results as their primary endpoints. Similarly, treatment time and volume can be used to help ensure that treatment is symmetrical.

We do not hesitate to add multiple sites for evacuation and final contouring to create a smoother, more uniformly treated area and to minimize the risk of contour deformities. As a general rule, we reserve superficial liposuction for patients who have significant superficial irregularities. Only surgeons with extensive experience in liposuction should perform this procedure because of the significant potential for skin injury and contour irregularities of the superficial soft tissues.

Finally, when contour irregularities are recognized intraoperatively, they are treated at this setting with autologous fat grafting at the site of the deformity. Trying to feather the edges of the defect most often leads to an even greater problem, further complicating its treatment.

Surgical Endpoints for UAL and SAL/PAL

Endpoint	UAL	SAL/PAL
Primary	Loss of tissue resistance Blood aspirate	Final contour Symmetrical pinch test results
Secondary	Treatment time Treatment volume	Treatment time Treatment volume

Cannulas and Probes*Traditional Suction-Assisted Lipoplasty*

Most traditional liposuction cannula tips are rounded and somewhat tapered to allow easier movement through the tissues. Most cannulas have multiple distal openings that are set back from the tip to avoid contour irregularities. These openings vary in size and are generally proportional to the diameter of the cannula. Multiple openings allow improved efficiency in fat removal. Single- and double-aperture cannulas are safe because the opening can be directed away from the skin; however, they do aspirate fat at a slower rate. The most common cannula type is the Mercedes, which has three apertures set back from the tip to allow efficient circumferential fat removal. There are multiple variations with either larger or smaller openings that can be tailored to the surgeon's preference or for a desired effect.

Power-Assisted Liposuction

An array of cannulas is also available for the PAL systems (Microaire Surgical Instruments, Charlottesville, VA). These cannulas are small and malleable, which is very useful when working along curved surfaces. They are comparable in length and diameter to SAL cannulas, which permit the use of small access incisions.

Ultrasound-Assisted Liposuction

Ultrasonic technology uses either a hollow cannula or a solid probe. Vaser probes (Sound Surgical Technologies, Louisville, CO) are solid and have rings circumscribing them. The rings allow lateral fragmentation; therefore the greater the number of rings, the more lateral fragmentation that is possible.

Vaser-Assisted Liposuction

Two- or three-ring probes are generally used in areas that have soft, nonfibrous fat, and the single ring probe is reserved for more fibrous secondary areas.

A cannula with a golf-tee-shaped tip allows greater fragmentation than a rounded bullet-shaped tip.

Cannula Size		
Site	Evacuation (mm)	Contouring (mm)
Neck	2.4	2.4 and 1.8
Arms	3.7	3.0 and 2.4
Back	3.7	3.0
Hips	4.6 (deep plane only)	3.7 and 3.0
Abdomen	3.7 (deep plane only)	3.7 and 3.0
Thighs	3.7 (deep plane only)	3.0
Knees	3.0	2.4
Calves/ankles	3.0	2.4

Treatment Areas

Arms

Upper arm contouring can be performed with any number of the modalities listed earlier. Caution must be exercised when suctioning toward the ulnar aspect of the elbow. The fatty layer is thin and mobile in this region, and the ulnar nerve courses superficially just beneath the investing fascial layer; this can be inadvertently injured during treatment, resulting in either temporary or permanent nerve injury. Arm thickness and composition of fat and muscle are variable; however, fat is usually most abundant in the posterior third of the arm.

Ideally, the arm is lean and has a convexity overlying both the deltoid and biceps muscles. On the posterior surface, the arm is slightly convex from axilla to elbow. Poor skin quality and/or excess skin will likely require excisional surgery. For patients who lack definition overlying the biceps and deltoid region, a circumferential approach to the arm may be preferable.

It is important to consider the area posteriorly where the arm joins the trunk. This region creates fullness with the arm in adduction and is often accentuated by a bra and/or other clothing. Liposuction of the arms is usually suited for patients with an excess of 1.5 cm of fat by the pinch test. Patients with less fat and more skin excess may benefit from excisional surgery rather than liposuction. The role of LAL in these patients has not been clearly defined.

Liposuction of the arms may be performed with the patient in either the supine or prone position. Regardless, care must be taken to avoid injury to the ulnar nerve, especially when using UAL. With UAL, the access incision is placed more radially around the elbow. Contouring on the ulnar side is reserved for SAL. If a patient requires circumferential liposuction of the arms or excisional surgery, we prefer to position the patient supine.

Proximal access may be achieved through a posterior axillary incision. The area where the arm joins the trunk may be accessed either through this incision or a back access incision in the case where the back is being treated as well. Overall, the fat is loose and areolar. The superficial nature of the fat requires the use of smaller cannulas. Evacuation begins with a 3.0 mm cannula and may transition to a 2.4 mm cannula for further contouring and feathering. In our hands, UAL tends to be particularly useful in the posterior third of the arm and the area adjacent to the back, because these areas tend to be more fibrous. PAL is also effective in these areas.

Back

The anatomy of the subcutaneous fat and skin in the back is uniquely different from other regions of the trunk and extremities; it has a very thick dermis and a dense, fibrous characteristic to the underlying fat. For liposuction in the back, we prefer to treat patients in the prone position with the bed in a head-down flexed position. UAL or PAL tends to work well in the fibrous tissue of the back. The quantity of fat removed can be moderate, but improved results are often observed with release of folds and attachments to deeper tissue. Access incisions will depend on the distribution of lipodystrophy and can be placed medially or laterally; the incisions should be placed in the bra/bathing suit line for the best cosmetic result. Forceful excursion of the cannula should be avoided, because fibrous areas may redirect the cannula to an unsafe location. Suctioning from areas off the thoracic cage (the hip region) toward the posterior back should not be performed to avoid intraabdominal penetration of the cannula.

Abdomen

The abdomen is bordered superiorly by the xyphoid process and costal margin, inferiorly by the pubis and inguinal ligament, and laterally by the anterior superior iliac spines. Lipodystrophy of the abdomen is predominantly seen in the infraumbilical region. Careful preoperative evaluation and physical examination are vital, with careful attention to the distribution of fat, scars, skin laxity, and the presence or absence of hernias. The physical examination may be challenging for patients who are overweight, those who have a large pannus, or patients with extensive scarring necessitating preoperative imaging to rule out any abdominal wall defects or hernias. Patients with diastasis, abdominal wall laxity, or significant intraabdominal fat should be counseled on the possible benefit and/or need for skin excision or plication to achieve an optimal contour and aesthetic result.

Subcutaneous abdominal fat is amenable to all of the various modalities of liposuction and continues to be one of the most desired areas for liposuction. We reserve superficial liposuction for the linea alba or for correction of secondary deformities. There have been published reports of superficial sculpting of the abdomen, *but we strongly urge that this be attempted only in experienced hands*. Overaggressive treatment of the abdomen, as with other regions, may result in untoward contour irregularities and/or skin injury.

Access to the abdominal region may be gained through an umbilical incision, bilateral lower abdominal incisions, and/or suprapubic incisions.

It is also useful to extend the table at the waist up to 15 or 20 degrees to allow excursion of the cannula from the suprapubic region. In patients with a long torso and a moderate degree of lipodystrophy overlying their costal margin, an inframammary fold incision can be made to access this fatty area. As with other body regions, *the surgeon should never approach an area of convexity from an area of concavity to avoid intraabdominal or thoracic penetration*. In the abdomen, it is imperative that short, controlled strokes be used to avoid the potential for inadvertent fascial perforation, particularly when working around scars.

Hips/Flanks

We often treat the hip/flank area with the patient in the prone position, although some surgeons prefer the lateral decubitus position. This common area of suctioning in both men and women is accessible through the bilateral or single midline paraspinous region and/or incision in the lateral gluteal fold. Suctioning in this area can provide excellent results, and all modalities have proved effective. The fat is loose and in some cases fibrous, with thick overlying skin. Significant striae may be seen in patients with weight fluctuations or in women who have had a child. Liposuction in these patients may reduce the lipodystrophy but can result in superficial contour irregularities or skin redundancy. Knowledge of the differing aesthetic considerations of the hips and flanks in men and women is crucial to preventing inappropriate masculinization or feminization. In general, men tend to have fullness in the superior and lateral region, whereas women usually have prominence more inferiorly and posteriorly.

In male patients the term *flank* describes an area immediately superior and posterior to the iliac crest. It begins in the paraspinous area and enlarges as it expands laterally. Anteriorly, the flank blends with the tissue of the lower abdomen. The inferior margin is defined by the zone of adherence along the iliac crest.

In contrast, the female hip is located more inferiorly and typically is centered over the iliac crest. The hip extends down to the level of the lateral greater trochanteric adherent zone. The fat in this region is typically loose but fibrous. The skin may be attenuated by striae and have some degree of laxity.

It is essential to mark the lateral gluteal depression before liposuction, because violation of this important area can lead to irregular contours and deformity. Often this adherent zone is a landmark to which both the hips and lateral thighs are reduced. In other patients, this area may be an area of significant depression that may benefit from autologous fat grafting.

The hip and flank can be accessed through two inferiorly placed lateral paraspinous incisions that are easily concealed by undergarments or a bathing suit. With more laterally displaced lipodystrophy, incisions may be moved more laterally. In contrast, patients with more posteriorly oriented fat may be adequately treated through a single lower midline access incision. This may be moved more superiorly if the fat overlies the area of the inferior posterior costal margin. However, it should be noted that this midline incision typically does not heal as well as paraspinous incisions do; this should be discussed with the patient. The lateral gluteal fold access incision may also contour the more inferior portion of the hip/flank, which allows an aesthetic blending between the lateral thigh and hip/flank area. This incision, in combination with a single midline access site, facilitates effective contouring and avoids incisions overlying the buttock area, which may have a tendency to dimple. However, caution should be used when contouring through the lateral gluteal fold incision, because overzealous resection through the trochanteric adherent zone is very likely to result in a contour deformity.

Thighs and Buttocks

Liposuction of the thighs is one of the more difficult procedures, where overaggressive treatment may result in an unsatisfactory contour. For most patients, a circumferential approach in the prone or supine position is best. Although patients may present with an isolated medial or lateral deformity, it has been shown that superior results are obtained with a circumferential approach, which provides the best contour and the highest patient satisfaction. The degree of contouring of specific regions of the thigh depends on the analysis and needs of each patient.

Because the majority of contour irregularities occur within the thigh region, again it is of paramount importance to recognize and understand the significance of the thigh zones of adherence: the lateral gluteal depression; the gluteal crease; the posterior, inferior, and distal lateral thigh; and the mid-inner thigh. In addition to these zones of adherence, the buttock area must also be approached with caution. A uniform reduction of the buttocks can be achieved through cautious treatment of the intermediate layer, resulting in a decrease in anteroposterior buttock projection. Access incisions are placed asymmetrically to avoid an operated look. Avoiding deep, aggressive suctioning and ensuring the length, position, and integrity of the inferior gluteal crease are of critical importance. Overzealous treatment in the deep or superficial plane may result in buttock ptosis. This area is most easily accessed through paraspinous or gluteal access incisions. Excessive contouring of the lateral proximal posterior thigh may result in an extension of the gluteal fold in women and masculinization of the gluteal area.

The surgeon must exercise special care when addressing the proximal posterior thigh. Aggressive suctioning in this difficult area may result in disfiguring skin rolls and redundancy. These problems can be very difficult to correct, requiring either autologous fat grafting or skin excision. In women, overtreatment of this area may elongate the gluteal fold, masculinizing the female silhouette. Suctioning of the lateral thigh and posterior thigh is easily facilitated through the previously described lateral gluteal fold access incision.

This 36-year-old patient underwent previous liposuction elsewhere and was unhappy with the appearance of her buttocks. Overzealous liposuction of the buttocks and proximal posterior thighs resulted in elongation of the gluteal fold and skin fold redundancy of the skin just caudal to the gluteal fold.

For evacuation and further contouring of the lateral thigh, a small midlateral incision may be made if necessary. Treatment of the posterior medial thigh is accomplished through the gluteal access incision with the patient in the prone position. If necessary, a second, more medial incision within the fold may facilitate treatment of this region.

With the patient supine, the anterior and medial thighs may be contoured through an inguinal crease incision and often an incision in the distal medial thigh. A shelf between the lateral and anterior thigh is often created when contouring the lateral thigh in the prone position. This transition should be treated and may be approached

through either the inguinal crease incision or a separate midlateral or anterolateral access incision. The anterior thigh has superficially located, relatively compact fat that has a tendency to develop contour irregularities. It is often necessary to treat the anterior thigh to allow adequate blending of the lateral and anterior thigh to avoid a shelf between the two regions. A more superficial approach within the femoral triangle will avoid injury to the lymphatic structures and prolonged lymphedema.

The medial thigh can be unpredictable with regard to redraping of the skin after liposuction. It is important to maintain a uniform, superficial layer of fat to prevent contour irregularities. Skin tone and quality need to be adequately assessed preoperatively so that the patient will have realistic expectations about liposuction of the medial thighs. In our experience, this is the most difficult area in which to achieve consistent results.

Knees

Treatment of the knees varies, depending on the patient's anatomy. Isolated fat of the knee medially is easily treated through a posterior incision with the patient in the prone position. For patients with suprapatellar fullness, the incision is usually placed within a skin fold anteriorly to adequately treat this fibrous area.

Neck

Liposuction in the neck region is often performed with traditional SAL and small cannulas or hand syringe suctioning. Access is typically via a submental incision and often is just posterior to the mandible on either side. Suctioning should proceed in a controlled fashion, and the superficial dermis should be avoided. Continuous assessment of contour is important. Overzealous treatment of this area may result in hollowing and skeletonization of the neck or potential neuropraxia of the marginal mandibular nerve. Fortunately, this is usually reversible and resolves within a few weeks of the procedure.

Results

This 36-year-old woman desired improvement in her abdomen, hips, and thighs. She underwent liposuction with UAL. A total of 3825 ml was infiltrated, and 3650 cc was removed. She is shown 5 months postoperatively.

This 60-year-old woman requested improvement in her abdomen, hips, and thighs. She was in good overall health and had some areas of skin inelasticity. The possibility of skin laxity was discussed with the patient, who wanted to look better in her clothing; 6100 ml was infiltrated and 6600 cc was removed. The patient was monitored overnight. She is shown 6 months postoperatively.

Preoperative

Imaging

9 months postoperatively

This 45-year-old patient had undergone liposuction of her abdomen and thighs approximately 10 years earlier. She had gained about 7 kg (15 pounds) since then and desired further improvement in her abdomen, hips, and thighs. She had some skin laxity of her abdomen but did not desire excisional surgery. She underwent secondary liposuction with UAL; 4300 ml was infiltrated and 4550 cc was removed. She is shown 9 months postoperatively. Particularly noteworthy is the final result in the posterior view.

This 47-year-old woman requested circumferential body contouring of her arms, back, hips, abdomen, and thighs. She underwent UAL/SAL of these regions. A total of 4750 ml was infiltrated and 5035 cc was evacuated. At 6 months postoperatively, her dress size has decreased from 12 to 8, and she has lost approximately 7 kg (15 pounds). Her circumferential trunk and thighs are improved, and modest improvement is seen in her abdomen.

This 32-year-old man requested improvement in his trunk. He underwent liposuction of the abdomen and flanks. A total of 1900 ml was infiltrated, and 1350 cc was evacuated. He is shown 1 year after surgery with improvement in the centralized lipodystrophy of his abdomen and the fullness in his flanks.

Adjunctive Uses of Liposuction

Breast Reconstruction

Liposuction can be a useful adjunct to many other procedures. During breast surgery it is often necessary to contour the lateral chest area. Liposuction may improve the contour and shape of the upper torso.

Flap Debulking

Liposuction may also be useful in flap debulking, specifically in breast reconstruction, as seen in this woman, who had 150 cc of fat removed from her transverse rectus abdominis musculocutaneous (TRAM) flap during a second-stage reconstruction. It is also very useful in treating TRAM flaps that have firm areas consistent with fat necrosis. Treatment may proceed without resorting to direct excision, thereby decreasing or minimizing skin incisions. In the past, these areas have not been amenable to treatment with SAL.

Postoperative Care

At the conclusion of surgery, patients are placed in an appropriate compression garment; some type of compression foam may also be used. In general, patients who have undergone any large-volume procedure (more than 5000 cc of aspirate), liposuction of multiple areas, or liposuction in addition to abdominoplasty or other excisional body contouring procedure are kept overnight for 23-hour observation. Patients are asked to ambulate the night of the surgery; sequential compression devices are placed on the patient in the preoperative holding area and are continued until discharge. The patient is allowed to shower beginning 1 or 2 days postoperatively.

and is instructed to wear the compression garment 24 hours a day for 2 weeks, removing the garment only for bathing. Initial postoperative visits are scheduled for 5 to 7 days postoperatively; the patient may return to activity and work as early as 3 to 4 days or 2 weeks, depending on the procedure. Walking is encouraged immediately, and light exercise is allowed 2 weeks after surgery, unless the patient underwent an associated abdominoplasty. Patients should expect to gain anywhere from 2.25 to 4.5 kg (5 to 10 pounds) after liposuction. Edema tends to peak 3 to 5 days after surgery; bruising should be minimal and dissipate by 7 to 10 days after surgery. Patients should begin to see contour changes in their waist by 2 weeks after the procedure and at 6 weeks be able to appreciate significant changes in their shape. As their activity level improves and necessary lifestyle changes proceed, further changes may be noticed. The final aesthetic result can be seen 3 to 6 months after surgery. Postoperative lymphatic massage is encouraged to help with swelling and induration and is often started before surgery and resumed shortly after the procedure.

Complications

Liposuction is not a procedure without risks. Much attention has been directed toward outcomes and prevention in the past few years, with the ultimate goal of improved results while maintaining patient safety. Complications can vary from mild postoperative nausea and vomiting to deep venous thrombosis/pulmonary embolism and even death. Complications can occur in the perioperative period, early postoperative period, and/or late postoperative period.

In a questionnaire to board-certified members of ASAPS, a significant increase in complications was reported when liposuction was combined with other contouring procedures, most notably when paired with abdominoplasty. Perioperative complications can include anesthesia and cardiac complications, cannula trauma to skin and/or internal organs, and volume loss or overload from bleeding or excess fluid administration. Cannula injury to blood vessels, bowel, and other solid intraabdominal organs has been reported in the literature. Although rare, these complications are related to incomplete preoperative examination (overlooking the presence of a hernia, for example) and overaggressive suctioning or penetration by the infiltration cannula. Hypothermia occurs commonly in liposuction cases. Hypothermia is generally defined as a core body temperature less than 36.4° C (97.5° F). It is common in anesthetized patients as a result of an interthreshold shift in thermoregulation. Its risk is amplified in larger volume cases in which a greater surface area of the patient is exposed at one time and patients are under anesthesia longer. The core body temperature can drop up to 2.8° C (37° F) in the first hours of surgery as a result of the anesthesia effect on autonomic regulation of core temperature. Warming of the wetting and preparation solutions, increase of the ambient temperature, and use of warming devices (Bair Hugger, Arizant, Eden Prairie, MN) all help reduce tem-

perature loss. Prewarming the patient with forced air for 1 hour has also been shown to significantly reduce the incidence of hypothermia.

Fluid management is crucial to the prevention of volume overload and anesthesia-related complications. As stated previously, careful management of intraoperative and postoperative fluids, as well as use of an intraoperative data sheet, helps prevent volume-related complications from liposuction. The tumescent liposuction technique has been implicated in volume overload and pulmonary edema; however, this can often be attributed to incorrect patient selection and/or poor fluid management. Fluid overload and untoward sequelae from large-volume liposuction (more than 5 L) prompted a warning by the ASPS that physicians performing liposuction should be trained in comprehensive fluid resuscitation and the physiology of large-volume liposuction.

Other early postoperative complications can include venous thromboembolism, infection, and skin slough or loss. The incidence of deep venous thrombosis in liposuction has been reported at less than 1%, but a marked increase in this percentage is demonstrated when liposuction is combined with other surgery (such as abdominoplasty or belt lipectomy). Physicians should familiarize themselves with the American College of Chest Physicians (ACCP) current recommendations and the modified Davison-Caprini Risk Assessment models currently available. Administration of enoxaparin has resulted in a decreased incidence of deep venous thrombosis but has been associated with an increased risk of perioperative bleeding and hematoma. Clinical signs of lower extremity swelling, Homan’s sign, shortness of breath, chest pain, and/or tachycardia should alert the provider to the possibility of deep venous thrombosis/pulmonary embolism and warrant immediate evaluation and treatment. Sequential compression devices are placed on all patients in the preoperative holding area and remain in place throughout the procedure and postoperatively while the patient is in bed until the time of discharge.

UT Southwestern Modification of Davison-Caprini Model			
Suggested Revisions to the Davison-Caprini Risk Assessment Model: Exposing Risk Factors			
One Factor	Two Factors	Three Factors	Five Factors
Minor surgery	Major surgery Immobilization Central venous access	Previous MI/CHF Severe sepsis Free flap Circumferential abdominoplasty	Hip, pelvis, leg fracture Stroke Multiple trauma

CHF, Congestive heart failure; MI, myocardial infarction.

Suggested Revisions to the Davison-Caprini Risk Assessment Model: Predisposing Risk Factors

	Number of Factors
Age 40-60 years	1
Age >60 years	2
History of venous thromboembolism	3
Current pregnancy	1
Current malignancy	2
Obesity	2
OCP/HRT	2
Hypercoagulable disorder	3

HRT, Hormone replacement therapy; OCP, over-the-counter progesterone.

Fortunately, wound infections and necrotizing soft tissue infections are rare but have been reported following liposuction. Persistent postoperative fevers and/or cellulitis should be closely monitored and aggressively treated. First-generation cephalosporins are administered perioperatively at our institution within 30 minutes of the incision unless the patient has a known history of methicillin-resistant *Staphylococcus aureus* (MRSA), in which case vancomycin is administered preoperatively.

Late complications of liposuction include delayed seroma formation, edema, ecchymosis, paresthesias, and contour irregularities. Seromas following aggressive liposuction are rare; they are thought to be caused by overzealous treatment of an area, denuding the fascia. It appears to be technique dependent rather than technology specific. A loose closure of cannula sites, postoperative compression garments, and expressing residual fluid over liposuction areas at the end of the procedure can potentially reduce the incidence of seroma formation.

Postoperative edema and ecchymosis occur to a varying extent in all patients. Prolonged edema may be present for up to 3 months after surgery and is best treated with supportive care and lymphatic massage. Postoperative paresthesia/dysesthesia can occur in all forms of liposuction. The sensory changes are usually reversible and can take up to 10 weeks to recover, but recovery is generally felt to be quicker with SAL than with UAL. Paresthesias in newer technologies have not been investigated.

The most common postoperative complication from liposuction is contour deformity or irregularities, which can occur in up to 20% of patients. Mild irregularities are often present after suctioning; these are treated conservatively with lymphatic massage as swelling and edema resolve. Once a contour deformity is identified, it is

best to determine the cause. Treatment can either be directed at reinjecting fat in the overresected region or suctioning the adjacent areas to reduce the prominence of the concavity and blending the adjacent areas. UAL has a decreased incidence of contour deformities compared with traditional SAL in our hands. We prefer UAL for secondary liposuction cases in which fat grafting is not indicated. Careful preoperative analysis and planning help to minimize the risk of postoperative contour irregularity, and thorough patient education about this potential and informed consent are essential.

Emerging Technology

Mesotherapy or lipolysis is an emerging technology, the goal of which is a reduction in fat by dissolution. The concept, which dates back to 1952, involves injection of phosphatidylcholine, deoxycholate, and/or other agents to dissolve fat deposits. It has gained popularity because of its “noninvasive” nature, and the marketing efforts have reached mainstream media and patients. Park et al showed no discernible difference after treatment in lower extremities with mesotherapy by measurement or CT evaluation. Lipodissolve is considered by some (but not all) practitioners to be a variant of mesotherapy. It involves injection of a standardized solution into the subcutaneous fat, rather than the mesoderm. The use of these products in the United States is controversial and is not supported by the FDA. A stern warning from the FDA cautions providers against its unproven use and false marketing claims. Several studies on safety and efficacy are available for review. The common side effects listed include hyperpigmentation and persistent pain; 12% of patients had cosmetic outcomes that were less favorable than expected. Further study and evaluation of safety on all forms of mesotherapy are warranted before clinical use can be endorsed.

Focused external ultrasound therapy is one of the most popular fat-reducing technologies currently being evaluated and has considerable popularity in Israel, Spain, and Japan. Depending on the technology, it can be thermally or non-thermally mediated (by cavitation). There is no “evacuation” phase; the process relies primarily on removal of fat by the body’s own phagocytic mechanisms. Preliminary data by Brown et al have shown it to be effective in a preclinical porcine model, in which the UltraShape device (UltraShape, Tel Aviv, Israel) was target specific for the adipocyte, preserving the surrounding neurovasculature. Two clinical studies have validated its safety. Currently the company is performing a multicenter, prospective, randomized, blinded study evaluating its safety and efficacy.

LipoSonix technology uses high-intensity focused ultrasound (HIFU) to disrupt fat in a thermally mediated mechanism. The device is currently undergoing clinical trials outside the United States and is being marketed in Europe. LipoSonix disrupts fat through a thermocoagulation-mediated mechanism (compared with UltraShape, which acts by cavitation, causing disruption of fat cell membranes). Neither the UltraShape nor LipoSonix is FDA approved or available in the United States.

Liposuction combined with radiofrequency ablation of fat cells is currently being investigated under the trade name BodyTite (New York). The purported benefits are thermal destruction of fat cells, removal via aspiration cannula, and subnecrotic heating of the dermis for skin tightening. This device is not currently approved by the FDA.

Cryolipolysis is a new and vastly different technology currently being evaluated for fat destruction under the trade name Zeltiq (Pleasanton, CA). The concept is a controlled cooling of the subcutaneous fat, with destruction of selective fat cells without epidermal or dermal injury. Zeltiq is currently undergoing evaluation but is not FDA approved.

Unfortunately, the devices mentioned here are still in the preliminary stages of development but represent exciting and novel approaches to noninvasive body contouring. We must keep in mind that until adequate scientific validation of these novel devices is performed outside of the manufacturers' influence, any discussion of potential benefit is strictly advertisement and market driven. As new technology is continually being introduced, we must temper our enthusiasm and base our treatments on solid, scientific evidence. Device manufacturers often provide scant, if any, objective data to support claims such as skin tightening, reduced pain, and improved aesthetic results.

Concluding Thoughts

Liposuction has evolved tremendously over the years since its initial description by Illouz. In the past 25 years there have been significant advances in the techniques and technologies available, resulting in improved safety and outcomes. We are confident that liposuction will remain one of the most popular procedures performed in the years to come. As each new therapy is developed, plastic surgeons must remain committed to the common goals of patient safety and improved aesthetic outcomes.

Clinical Caveats

It is useful to classify patients based on their degree of lipodystrophy and skin redundancy.

Recognition of the zones of adherence is essential. These areas are vulnerable to contour irregularities.

The patient's taking over-the-counter herbal and diet medications may have unfavorable interactions with anesthetics and/or consequences for surgical outcomes.

The intermediate fatty layer is the most common layer treated.

Superficial liposuction should be reserved for significant superficial irregularities and be performed by those experienced in liposuction techniques.

One should avoid treating convexities from adjacent concavities.

The utilitarian access site for UAL is the lateral gluteal fold.

Patients with surgical scars on their abdomen must be thoroughly examined to rule out the presence of a hernia.

Treatment with UAL begins superficially and ends in the deeper plane. In contrast, evacuation proceeds from the deeper layers to the more superficial layers.

The compression garment should first be removed with the patient in the supine position to avoid a vagal response.

Incorporation of a diet and exercise program in conjunction with liposuction will allow patients to achieve their optimal shape and contour.

CHAPTER 79

Screening and Safety Issues in the Massive-Weight-Loss Patient

JOSEPH F. CAPELLA, MATTHEW J. TROVATO,
SCOTT WOHRLE

Postbariatric patients represent a distinct population of plastic surgery patients. Unlike routine body-contouring candidates, who are usually healthy and have relatively mild deformities, postbariatric patients frequently have a history of significant illness and virtually all have major contour deformities. The techniques for managing facial aging and characteristic body contour deformities of most postpartum women have become well honed through decades of plastic surgery training. Many of the body-contouring procedures for treating patients after massive weight loss are relatively new and are evolving quickly, and few plastic surgeons have had significant exposure to them during training. It is also generally recognized that postbariatric procedures are associated with higher rates of complications. The combination of improved techniques in bariatric surgery and a worsening epidemic of obesity in the United States has led to a significant increase in demand for body-contouring procedures. Thus it has become increasingly important for plastic surgeons to have a protocol in place to screen and manage these individuals safely.

Effective evaluation of postbariatric patients requires some familiarity with morbid obesity and the surgical procedures commonly available to treat this condition. Most morbidly obese individuals have been obese since adolescence, and some even since childhood. These patients often have a number of comorbidities, including hypertension, diabetes mellitus, sleep apnea, and urinary incontinence.

Conditions Associated With Morbid Obesity	
Asthma	Hypertension
Back and disc disease	Increased risk for carcinomas
Cardiac and peripheral vascular disease	Intertriginous dermatitis
Cholelithiasis	Male and female endocrine and reproductive disorders
Depression	Obesity hypoventilation syndrome
Diabetes mellitus/impaired glucose tolerance	Peripheral osteoarthritis
Dyslipidemia	Peripheral venous insufficiency
Fatty metamorphosis, cirrhosis, and carcinoma of the liver	Pseudotumor cerebri and carpal tunnel syndrome
Gastroesophageal reflux disease	Sleep apnea

Following weight loss, these conditions may be cured, improved, or stabilized. Last year more than 220,000 surgical procedures were performed in the United States to treat morbid obesity. The present criterion (suggested by the National Institutes of Health and adapted by health insurance providers) for surgery requires that patients have a body mass index (BMI) of 40 or greater. Those with a BMI as low as 35 may qualify if they have a disease-related comorbidity, such as hypertension or diabetes mellitus. Many variations of bariatric procedures have been performed over the past several decades. At present, gastric bypass surgery is the benchmark procedure and is the most commonly performed. Ten years ago, gastric bypass was usually performed as an open procedure; today it is commonly done laparoscopically.

In recent years laparoscopic adjustable gastric banding (LAGB) has gained popularity. In some centers, it is now the most commonly performed bariatric procedure.

A less common procedure is biliopancreatic diversion with duodenal switch (BPD-DS). Each of these techniques is associated with different rates of weight loss and complications. Therefore each procedure has separate implications for plastic surgeons.

Gastric bypass surgery produces rapid weight loss during the first 8 to 10 postoperative months, with some patients reaching their lowest weight during this time. Generally, patient weights stabilize 12 to 18 months after the operation. Weight loss with this procedure is achieved through the restriction of food intake and some degree of malabsorption.

Average weight loss following a standard gastric bypass procedure is 60% to 65% of excess weight at 5 years postoperatively and 77% with the banded form of gastric bypass. At 5 years, the typical patient has regained approximately 10% of the excess weight lost. Particularly during the rapid phase of weight loss, gastric bypass patients may have hypoproteinemia. Iron- and folate-deficiency anemias are very common among women after gastric bypass, particularly menstruating women. These side effects can be further complicated by abnormal and frequent vomiting. Supplementation with multivitamins, iron, folate, thiamine (B_1), B_{12} , and calcium is usually prescribed.

After the open form of gastric bypass, incisional or ventral hernias can be found clinically in as many as 10% of patients. This number may be slightly higher on exploration of the abdominal wall fascia during a body-contouring procedure. These forms of hernia rarely lead to bowel obstruction. Internal hernias are a concern after laparoscopic gastric bypass surgery. Most likely because of minimal adhesion formation, after a laparoscopic gastric bypass operation the small bowel has a greater tendency to herniate through mesenteric defects. The frequency of internal hernias appears to be highest during the period patients usually reach their lowest weight, 18 to 36 months postoperatively—often when body-contouring procedures are being performed. A high index of suspicion is necessary to diagnose a hernia promptly. Patients may present with episodic bouts of moderate to severe pain as the bowel becomes partially or completely strangulated in the hernia. Surgeons must not attribute pain of this nature to routine postoperative discomfort. A late diagnosis can lead to necrotic bowel and possibly death.

Various forms of obstruction after gastric bypass surgery are shown: twisting of the bowel around isolated bands or adhesions, incarcerated incisional hernia (trocar hernia), scar formation or fibrosis at the mesenteric defect, and bowel obstruction without a closed-loop component caused by adhesions. Twisting of the bowel, incisional hernia, and scar formation or fibrosis are more common after laparoscopic gastric bypass surgery. Bowel obstruction without a closed-loop component caused by adhesions is more common following open gastric bypass surgery.

In LABG, an adjustable silicone ring is placed around the stomach immediately below the esophagogastric junction. A filler tube from the band traverses the abdominal wall and is connected to a port that is secured to the abdominal fascia and is accessed by transcutaneous injections. The gastric band is inflated and deflated by adding and removing saline solution. Typically the port is placed in a paramedian position, often subcostally. Weight loss is achieved purely through the restriction of food intake and is much slower than with a gastric bypass procedure. A stable reduced weight may take as long as 3 years to achieve. On average, LABG patients have lost 30% to 54% of their excess weight at 5 years postoperatively. The nutritional disorders described for gastric bypass patients are also associated with LABG but are generally less severe, unless there are complications. The band may move from its desired position or cause a stricture, leading to excessive narrowing of the stomach and subsequent vomiting. Some dilation of the esophagus may occur in many gastric-banding patients. The plastic surgeon and anesthesiologist should be aware of this, because aspiration may be of particular concern during intubation.

BPD-DS produces weight loss by some degree of food intake restriction and significant malabsorption. The technique is effective, with patients averaging 73% loss of excess weight at 5 years. However, this procedure is associated with more significant nutritional deficiencies than the two previously described techniques. In particular, the absorption of calcium, vitamin D, protein, and fat-soluble vitamins is more affected. The relatively large gastric pouch resulting from this procedure may allow patients to consume foods at their presurgical rate, leading to frequent, foul-smelling, bulky stools and significant diarrhea.

Postbariatric patients will differ in their comorbidities and postoperative status; some may have significant residual disease from morbid obesity, and others will not. In addition, sequelae from bariatric surgery will vary from patient to patient. An understanding of morbid obesity and bariatric surgery will help the surgeon determine the appropriate management of each massive-weight-loss patient.

Screening

My approach to screening and evaluating postbariatric patients involves a minimum of two office visits: an initial consultation and a preoperative visit, and at least one outside consultation. Throughout this process, patients are encouraged to communicate concerns to the office and to include family members, loved ones, and caregivers.

Initial Consultation

The initial consultation serves multiple purposes: I establish rapport with the patient, obtain a medical and social history, perform a physical examination, and gain an understanding of the patient's goals. Ideally, at the conclusion of this first visit, a preliminary plan can be provided to the patient.

History

Along with a medical and social history, a detailed weight history should be obtained (see p. 2805). Critical information includes the patient's height, current weight, and highest weight. The interval between his or her highest and current weights and the length of time at the current weight should be documented. If weight loss was achieved through bariatric surgery, the technique and when it was performed should be noted. Other important information includes whether the individual is being followed by a bariatric surgeon and the date of the patient's last visit. If supplemental medication was prescribed, is the patient taking it regularly? Problems potentially related to bariatric surgery should be explored, such as frequent vomiting, abdominal pain, weakness, light-headedness, and frequent bowel movements. For patients who have lost weight through lifestyle changes, how this was accomplished should be documented—exercise, diet and exercise, or medication—and whether the patient is being supervised by a professional.

Physical Examination

The examination of a postbariatric patient should be thorough, with particular attention to areas typically affected by weight loss. A standardized examination form is helpful (see pp. 2806-2807). The presence of intertriginous dermatitis should be noted. Lymphedema and/or the stigmata of lymphedema are documented, as are varicosities. Existing scars should be described, particularly abdominal scars. The surgeon should assess for abdominal wall hernias. This portion of the examination can often be challenging because of the presence of a large pannus. Routine maneuvers to identify hernias, such as having the patient attempt to sit up from a supine position, can be very helpful.

Patient Goals

The average patient age in my postbariatric practice is 39. Most of these individuals are very active and eager to minimize their time off from work and time away from family obligations. It is quite common for a patient to express concerns about multiple areas of the body and to ask how quickly all of the areas can be addressed. Perhaps the most important component of screening and minimizing risk in a postbariatric patient is the selection of the most appropriate procedure or combination of procedures and their sequence.

PATIENT INTAKE FORM: WEIGHT INFORMATION

Patient name _____ Date _____

Height _____ Current weight _____ Highest weight _____

Length of time to achieve current weight _____

Length of time at current weight _____

METHOD OF WEIGHT LOSS**1. Bariatric surgery**

Date of surgery _____

a. Gastric bypass: Open _____ / Laparoscopic _____

b. Laparoscopic gastric banding _____

c. Biliopancreatic diversion _____

d. Gastric sleeve _____

e. Vertical banded gastroplasty _____

2. Lifestyle change

a. Diet _____

b. Exercise _____

Formulating a Plan

The information gathered by the patient history and physical examination can now be used to formulate a preliminary plan. The patient's BMI at presentation is one of the most important variables in determining the appropriate course to take in managing a postbariatric patient's contour deformities. My data from the body-lift procedure indicate that individuals with lower BMIs at the time of body-contouring surgery have fewer complications.

BMI and Outcome Data Associated With Body Lift

	Patients	Percentage	LOS (days)	Drain Duration (days)	Complications (%)	Dehiscence (%)	Seroma (%)	Skin Necrosis (%)	Infection (%)	Bleeding (%)	DVT (%)	PE (%)	Transfusions (%)
Total	425*	100.00	2.74	23	49.65	27.29	20.94	8.47	4.94	2.59	2.35	1.18	12.94

Type 1: BMI <28; type 2: BMI ≥28 and <32; type 3: BMI ≥32.

*Body lift: A simultaneous abdominoplasty with a thigh and body lift.

DVT, Deep venous thrombosis; LOS, length of stay; PE, pulmonary embolus.

I prefer to perform a body lift first as a single procedure, then follow with a combination mastopexy/flankplasty/brachioplasty at least 3 months later. A medial thigh lift, if necessary, would be done at least 3 months after that. Although I think the aesthetic results may be best with this combination and sequence of procedures, primarily because opposing vectors of tension are avoided, many individuals request that their management be limited to two operations, or even one. In an effort to accommodate patient wishes and minimize complications, I make different options available based on BMI. For individuals with a BMI of less than 28, I consider per-

forming upper body work along with a body lift and in some instances a medial thigh lift. For those with a BMI between 28 and 32, upper body work is considered with a body lift, and for those with a BMI above 32 and below 35, I advise a procedure limited to a body lift. Individuals with a BMI greater than 35 are usually candidates for an abdominoplasty rather than a body lift. In this heaviest group of patients, I often consider avoiding fascial plication to facilitate early ambulation.

Contouring Options Available to Appropriate Candidates

BMI <28	BMI 28 to 32	BMI ≥32	BMI >35
Body lift (combination abdominoplasty, thigh and buttock lift)	Body lift	Body lift	Abdominoplasty alone (possibly without fascial plication)
Mastopexy/flankplasty/brachioplasty combination	Mastopexy/flankplasty brachioplasty combination		Body lift alone (possibly without fascial plication)
Medial thigh lift			

BMI criteria are less important for individuals seeking specific upper body procedures alone, such as mastopexy, brachioplasty, and facial procedures. I avoid performing facial procedures with extensive body contouring. A surgeon's experience as well as those assisting in the surgery should factor into what the appropriate approach should be.

Before a patient is considered for any procedure, certain criteria must be met and issues addressed. The patient should be at a stable weight for at least several months. This will vary, depending on the bariatric procedure. Operating during a period of active weight loss may result in an early recurrence of soft tissue laxity, and from a safety perspective, the patient's nutritional and metabolic status is unlikely to be optimal. Patients with symptoms indicating problems related to bariatric surgery should be evaluated by their bariatric surgeon. Those with a history of major or acute mental illness are referred for evaluation by an appropriate health professional. Patients are advised to maintain the supplemental regimen prescribed by their bariatric surgeon. Individuals who use tobacco are urged to stop as soon as possible. The risks of tobacco regarding wound healing and thromboembolic disease are clearly established in the literature and are explained to the patient. I prefer to have patients stop taking any medications that are part of their weight-loss protocol. All patients are referred for medical clearance. Although weight loss dramatically improves the health of morbidly obese individuals, not all medical conditions are resolved by weight loss. Neurologic problems are not uncommon following bariatric surgery, potentially affecting both the central and peripheral nervous systems. Foot drop has been reported following weight loss, and peripheral neuropathies have been described after rou-

tine postbariatric body-contouring procedures in which standard positions and precautions have been used. A careful evaluation of their health is imperative. A consultation with a general or bariatric surgeon may be requested if an abdominal wall hernia has been found.

After I discuss the proposed plan with the patient, we review several topics together. Many individuals are eager to lose more weight before they undergo surgery in the belief that their surgery would be safer and that more skin could be removed if they were at a lower weight. I think that most people whose weight is stable (variation of less than 10 pounds for 3 to 6 months) at the time of consultation are at the weight they are most likely to maintain over the long term. Although many postbariatric patients can lose weight for relatively brief periods—several months, perhaps a year—long-term additional weight loss after bariatric surgery or through lifestyle changes is difficult to achieve. An individual losing weight in short period of time can have several undesirable outcomes. First, he or she may become nutritionally and metabolically unbalanced just at the time body-contouring surgery is to be performed. Second, weight gain in the future will in most instances diminish the aesthetic results of a body-contouring procedure. I advise patients to eat a balanced diet and maintain a stable weight.

I explain that a certain amount of excess soft tissue will be removed during surgery. Their new weight after surgery should be their current weight minus the weight of the tissue removed. If their weight at their 3-month postoperative follow-up is similar to their weight at consultation, this suggests a significant weight gain. I also explain that there will inevitably be some recurrence of skin laxity and that the long-term results of surgery are best maintained by weight stability, avoiding tobacco use, and minimizing exposure to sun (UV light). Scars should not be exposed to UV light while they remain pigmented; UV light will cause or prolong further pigmentation. Once scars have faded to the color of the surrounding skin, they may be exposed to UV light without risk of hyperpigmentation. In general, UV light always accelerates the aging (or damage) of skin. I conclude by giving patients an overview of the most frequent complications associated with each procedure and the relevance of BMI.

Laboratory Workup

A patient history can often suggest problems; however, a thorough laboratory workup is essential for identifying existing deficiencies or abnormalities. It is not unusual for menstruating women to have few if any symptoms despite having severe anemia after bariatric surgery. Along with a complete blood cell count and other studies, our routine includes a complete metabolic panel. Abnormal laboratory values are acted on as they are made available. Individuals found to be malnourished, with a total protein level less than 6 g/dl and/or albumin level less than 3 mg/dl, may be referred to their bariatric surgeon for reevaluation and possible nutritional supplementation. Those findings may be corroborated by edema on physical examination. Protein-depleted patients may have difficulty with wound healing. Severely anemic patients,

those with a hemoglobin less than 10 g/dl, are referred to their primary physician and/or a hematologist. Patients with a hemoglobin level above 10 g/dl are advised to continue on iron, folate, and B₁₂ supplementation and to have their blood cell count repeated in a week. Our preference is for patients to have a hemoglobin level above 12 g/dl before surgery.

Patients are advised of the possible need for a blood transfusion after the operation. I do not have patients bank their own blood. In most institutions, blood can only be given within 1 month of surgery, and 1 month may not be adequate for an anemic patient to replenish his or her blood levels.

Preoperative Visit

At the preoperative visit, usually 2 weeks before surgery, the planned surgical procedure is reviewed in detail, as are the potential complications. The results of requested consultations and recommendations are discussed with the patient. Another critical function of the preoperative visit is to review photographs taken at the first consultation. Patients rarely have a completely accurate sense of their deformities. Key elements of this discussion are to highlight existing asymmetries, which in some cases cannot be completely corrected; review the extent of their deformities; and explain the degree to which the planned procedure or procedures will address their deformities. I prefer not to morph patient images on the computer but rather to show examples of individuals with similar body types who have had the same procedures. Restrictions and recovery guidelines are reviewed. Patients often have the sense that recovery from surgery should involve a lengthy period of bed rest. I emphasize the importance of frequent ambulation. Medications that should be avoided before surgery are reviewed: those that increase the risk of bleeding, such as aspirin and non-steroidal antiinflammatory agents, and those that increase the risk of DVT, such as birth control pills or hormone replacement therapy. Patients are advised not to take any of these medications for 2 weeks before or after surgery. I conclude with a plan for DVT prophylaxis.

Deep Venous Thrombosis Prophylaxis

My approach to DVT prophylaxis is derived from my own data and currently suggested guidelines. My experience confirms the published reports that abdominoplasty creates a significant risk for DVT. Having performed routine lower extremity venous Doppler studies on well over 400 postabdominoplasty patients, I have found a correlation between the patient's presenting BMI and the likelihood of thromboembolic disease (see the table on p. 2808). Therefore, in my practice, patients undergoing an abdominoplasty or body lift alone or with additional procedures and who have a BMI of less than 28 on presentation are not given chemoprophylaxis preoperatively or postoperatively. Instead, a lower extremity venous Doppler study is performed before discharge from the hospital, typically 1 or 2 days postoperatively. Those with a BMI between 28 and 32 are given enoxaparin 40 mg subcutaneously beginning

approximately 12 hours after surgery and each day during their stay in the hospital or recovery facility. Once again, a lower extremity venous Doppler study is performed before discharge. Patients with a BMI above 32 who are undergoing abdominoplasty and/or a body lift follow the same regimen as the previous group but are kept on enoxaparin 40 mg subcutaneously for 10 to 14 days after surgery. Patients with a BMI greater than 32 undergoing a single procedure, such as mastopexy, brachioplasty, or a combination of the two, are given a single preoperative dose of heparin 5000 units subcutaneously before surgery. I perform these procedures or the combination of the two on an outpatient basis. For the combination of brachioplasty, mastopexy, and medial thigh lift, patients with a BMI above 32 are given enoxaparin 40 mg subcutaneously 12 hours after surgery. These patients are typically observed overnight. Lower extremity venous Doppler studies are not routinely performed in non-abdominoplasty/body lift patients. I have chosen not to provide chemoprophylaxis to all patients because of anecdotal observations about increased bleeding with these medications. For similar reasons, ketorolac tromethamine is not used. Patients with a history of DVT and/or PE, a family history of thrombosis or blood-clotting disorders, varicose veins, lower extremity swelling, and recent air travel should be managed on a case-by-case basis.

Deep Venous Thrombosis, Chemoprophylaxis, and Surveillance

	BMI <28	BMI 28 to 32	BMI ≥32
Abdominoplasty or body lift with or without other procedures	No perioperative chemoprophylaxis Lower extremity venous Doppler exam on POD 1	Enoxaparin 40 mg 12 hr postoperatively Lower extremity venous Doppler exam on POD 1	Enoxaparin 40 mg 12 hr postoperatively Lower extremity venous Doppler exam on POD 1 Enoxaparin 40 mg SQ for 14 days postoperatively
Brachioplasty, mammoplasty, thighplasty (any of the procedures alone or a combination of two)	No perioperative chemoprophylaxis	No perioperative chemoprophylaxis	Heparin 5000 units SQ preoperatively (patient usually discharged home)
Brachioplasty/mammoplasty/thighplasty combination	No perioperative chemoprophylaxis	No perioperative chemoprophylaxis	Enoxaparin 40 mg SQ postoperatively (patient usually observed overnight)

POD, Postoperative day; SQ, subcutaneously.

Perioperative Management

Preoperative

Before surgery, patients are marked and scar locations are reviewed, usually for the third time. In cases in which a mastopexy/reduction is being performed, I have the patient reconfirm her desired breast size. If chemoprophylaxis is to be given, it should be administered at this time. If shaving is to be performed, usually the redundant mons pubis, it should be done now. Patients are discouraged from shaving in the 48 hours before surgery to diminish the risk of skin infections.

Intraoperative

Intraoperatively the focus is on minimizing the length of procedure, patient exposure, blood loss, proper patient positioning, and DVT prophylaxis. The room is kept at a comfortable temperature for the patient, usually at least 24° C (75° F). The patient's skin is cleansed while standing with povidone-iodine (Betadine) to minimize the time spent preparing and draping during a surgery involving multiple areas. Sequential compression devices are placed and activated before induction of anesthesia. Intravenous antibiotics are given immediately after placement of the intravenous catheter. Fluids are warmed, and a Bair Hugger and operative table warming blanket are used whenever possible. Blood loss is kept to a minimum by meticulous hemostasis and the use of two electrocauteries, for the surgeon and assistant, set to a relatively high level. Pressure points are carefully padded, and extremities are positioned cautiously during maneuvers to rotate the patient.

Certain circumstances may arise during surgery, some planned and others not, that must be addressed. A post-LAGB patient will have a port that nearly always must be moved to effectively address abdominal wall fascial laxity. Routine midline plication of the abdominal fascia in an LAGB patient may render the port inaccessible. In these patients, the port should first be detached from the fascia by dividing the nonabsorbable sutures. The plication should then be performed as usual, with careful attention to the tube location and verification throughout the process that the tube can move freely. After plication, the port should be resecured with nonabsorbable sutures in a subcostal position. The prominence of the costal margin makes the port less discernible. Lower-BMI individuals may have concerns about the perceptibility of the port. In these patients, the outline of the port may be visible along the anterior abdominal wall. The port may be exchanged for a lower-profile version. If this is to be done, the lower-profile port should be available preoperatively, and obtaining the assistance of a bariatric surgeon for the exchange should be considered.

Ventral hernias may be discovered during elevation of the abdominal pannus that were not evident during preoperative evaluation. I have found that for small incisional fascial defects, where preperitoneal fat is adherent to the fascial edges, no particular maneuver is necessary. The fascial plication can be performed as usual, with the sutures carefully placed through the rectus sheath overlying the rectus muscle. Rectus diastasis can be considerable in these patients. For larger fascial defects, particular those in which the hernia contents readily protrude through the defect, repair is required. The hernia sac contents are separated from the hernia sac, the fascial edges are approximated without tension, and a standard plication is performed. Routine hernias (those not involving a loss of tissue) in a postbariatric patient rarely require mesh for repair. An intraoperative consultation may be sought if an unexpected hernia is discovered.

Postoperative

In the immediate postoperative period, the patient should be assessed for anemia, hypovolemia, and hypothermia. Warming techniques like those used during surgery should be used. Vital signs, urine output, and drainage output should be monitored closely. Only three postoperative doses of antibiotics are routinely given. Following postbariatric body-contouring procedures, significant blood loss may occur from oozing. Tissue surfaces with the potential for bleeding can be extensive. Drains can help to monitor this. Ideally, the fluid in the drains should take on a watery consistency and pinkish color soon after the procedure. A thick consistency and dark red color is a reliable indicator of continued bleeding. Although a routine CBC may not be necessary, blood should be drawn for this purpose if there is any question of anemia and/or hypovolemia. The initial CBC usually does not reflect the actual blood loss that has taken place. I prefer to maintain hemoglobin levels above 8 g/dl.

Aggressive DVT prophylaxis should be continued postoperatively. In addition to the protocol just described, all patients should have sequential compression devices in place until they are ambulating regularly. Ambulation with assistance is attempted the evening after surgery. Some patients may experience light-headedness despite being adequately resuscitated; narcotics are the likely cause. Initial attempts at ambulation should always be done with assistance—a syncopal episode without supervision can easily result in head trauma. Patients are strongly encouraged to shower for the first time with supervision. A warm shower can induce a syncopal episode. Following discharge from the hospital, postbariatric body-lift patients remain at risk for a wide array of complications; DVT and pulmonary embolism represent the most important potential problems. A high index of suspicion is the safest approach to thromboembolic disease. Physical findings or patient reports of lower extremity

swelling and/or discomfort, particularly unilaterally, should be evaluated promptly. The signs and symptoms associated with DVT and pulmonary embolism are many and should be familiar to all physicians.

It is not unusual for patients to become depressed several weeks after surgery; particularly after major procedures such as a circumferential body lift, the patient may regret having chosen to have the operation. In some cases, patients remark that they are not even sure why they are depressed. I have found it very helpful to inform patients that this is normal and will most likely resolve over the next several weeks. Our patients are encouraged to contact other patients who have had similar procedures to discuss their experiences. Discussions with other patients can be helpful for understanding different emotional states following surgery.

Concluding Thoughts

Body contouring of the postbariatric patient can be a gratifying experience for both the patient and plastic surgeon. To achieve this end, every effort must be made to minimize risk and avoid complications. The surgeon must thoroughly understand morbid obesity and the procedures to treat this condition and should implement a screening protocol that identifies patients who are satisfactory candidates for surgery. Candidates should then be offered the appropriate procedures in the appropriate sequence. The patient's BMI should be considered as one of the primary variables in the decision process. Finally, the perioperative care of these patients must be meticulous and involve great dedication by the plastic surgeon.

Clinical Caveats

A postbariatric patient's BMI is the most important factor for determining appropriate management of contour deformities.

There is a correlation between a patient's presenting BMI and the likelihood of thromboembolic disease.

A patient's weight should be stable for several months before a body-contouring procedure is performed.

A thorough laboratory workup, including a complete blood cell count and a metabolic panel, is essential before body-contouring surgery.

CHAPTER 80

Brachioplasty

JOSEPH F. CAPELLA,
MATTHEW J. TROVATO, SCOTT WOHRLE

The rapid growth in bariatric surgery over the past decade has led to an increase in demand for surgical procedures to address the contour deformities of the arm following massive weight loss. According to the American Society of Plastic Surgeons, from 2000 to 2008 there was a 4059% increase in the number of brachio-plasty procedures performed in the United States. Although weight loss affects the entire body, the arms for many individuals are often of greatest concern because of their visibility during everyday activities. The arm deformity associated with weight loss is often dramatic and is influenced by multiple factors, including patient body mass index (BMI); highest BMI ever obtained; change in BMI; age; and sex.

In a morbidly obese individual, fat deposits are usually most prominent along the axilla and the anterior, posterior, and medial arm.

After weight loss, these regions of the arm manifest the greatest excess in soft tissue. Patients with a lower BMI, particularly those who had reached a very high BMI before weight loss, are likely to have more soft excess than an individual who has had a smaller change in weight.

Older patients, particularly women, perhaps because of attenuated connective tissue, often have large amounts of excess tissue despite relatively small changes in BMI. In men, the majority of their deformity tends to be limited to the proximal arm and axilla. Women may have this appearance as well but are more likely to have a deformity that extends to the elbow and beyond.

Evolution of Technique

Before 2000, brachioplasty procedures were rarely performed by most plastic surgeons. The earliest descriptions of brachioplasty were relatively simple techniques involving the removal of an ellipse of soft tissue. The axilla was not addressed, and candidates for surgery were usually moderately overweight individuals. In the 1970s, multiple articles were published that described different patterns of excision for soft tissue of the arm. Several of these publications included techniques to avoid scar con-

tracture at the arm-axilla transition. Pitanguy described addressing deformities of the axilla and lateral thoracic region concurrent with correction of excess tissue of the arm. The first case report of a massive-weight-loss patient undergoing brachioplasty was published in this period. In the 1980s, articles appeared on performing brachioplasty as part of an upper body lift and near-total body lift, and Goddio reported on an innovative technique of burying soft tissue excess. Brachioplasty continued to evolve in the 1990s. Liposuction became a more integral component of these procedures. Lockwood proposed that the posteromedial soft tissue of the arm is suspended to the clavipectoral periosteum by means of the clavipectoral fascia and axillary fasciae. He argued that when these structures loosen, they lead to a “loose hammock” effect, or arm ptosis. Lockwood’s technique for brachioplasty described securing the arm flap to the axillary fascia and incorporating a superficial fascial system repair in wound closure to help reduce the incidence of wide scars and unnatural contours.

In the past decade, many articles have been written on brachioplasty. In an effort to minimize scar length, several authors have described excisional techniques limited to the axilla and proximal arm in combination with liposuction. The majority of recent articles on brachioplasty involve weight-loss patients almost exclusively, and the size of the series analyzed has increased considerably from that of a decade ago. Much of the discussion today in the literature is on scar position, the timing and use of liposuction, and incorporation of short-scar techniques in the management of postbariatric patients.

Scar Placement, Use of Liposuction, and Scar Length

Advantages and disadvantages can be proposed for the various recommendations regarding scar placement, the use of liposuction, and short-scar versus traditional scar techniques. Scar location in brachioplasty is often the most important consideration for postbariatric candidates, and one of the most frequently discussed topics among plastic surgeons. Traditional locations range from the bicipital sulcus to the posterior aspect of the arm. Advocates of a more posterior approach argue that scar visibility is diminished in this location. Proponents for the bicipital sulcus prefer this location for the same reason.

The use of liposuction in brachioplasty is often debated. Some argue that liposuction should be performed before an excisional procedure. These surgeons advocate a staged approach. Liposuction is performed first to “debulk” the arm, and at a later date an excisional procedure is performed. Those recommending the concomitant use of liposuction argue that liposuction reduces arm volume and provides greater

tissue mobilization without damaging nerves and other vessels. Various approaches have been suggested to address the postbariatric arm deformity with a scar limited to the axilla or extending only partially down the arm. Advocates argue that some postbariatric patients have limited arm deformities that can be effectively addressed with scars only in the axilla or axilla and proximal arm, usually in combination with liposuction. The obvious advantage is that a scar is avoided in the far more visible middle and distal thirds of the arm. Proponents of the classic approach, scar extension to the medial epicondyle, would argue that a limited approach to most postbariatric patients leads to suboptimal results.

Our Approach to Brachioplasty

We prefer to use a posteromedial approach with extension to the medial epicondyle in combination with liposuction in the vast majority of massive-weight-loss patients. In the first half of our series, our scars were placed along the bicipital sulcus. We have not found that an approach limited to the axilla or proximal arm was effective for a significant number of individuals in this patient population.

Indications and Contraindications

The best candidates for brachioplasty are healthy individuals who have achieved a stable weight, have a BMI of less than 28, and who have lost substantial weight, generally more than 23 kg (50 pounds). Dramatic results can be achieved in individuals with a BMI greater than 28; however, the final aesthetic result is less likely to be ideal. The value of performing a brachioplasty depends greatly on the extent of the deformity to be corrected, which in turn usually depends primarily on the degree of weight loss. Variables representing relative contraindications to brachioplasty are high patient BMI and a small BMI change from the highest weight; significant patient reservations regarding arm scars; a history of poor scars, such as hypertrophic or hyperpigmented scars; and unrealistic patient expectations, particularly with regard to short-scar versions of brachioplasty. In our practice at present, absolute contraindications are a history of lymphedema and/or arterial or venous insufficiency of the upper extremity. A high risk for developing one of these conditions, such as a patient who has undergone axillary lymph node dissection or radiation, would also represent an absolute contraindication for brachioplasty.

Patient Profiles

This 25-year-old woman, who lost 58 kg (128 pounds) as a result of bariatric surgery, was an ideal candidate for brachioplasty. She presented 4 years after surgery at a weight of 62 kg (137 pounds); her highest weight before bariatric surgery was 120 kg (265 pounds). Liposuction was performed along the posterior and medial aspects of her arms immediately before tissue undermining and excision. No liposuction was performed at the axilla. The scar was placed along the posteromedial aspect of the arm in an effort to minimize visibility.

This 31-year-old woman lost 92 kg (203 pounds) following bariatric surgery. She presented 4 years after surgery at a weight of 88 kg (195 pounds); her highest weight before bariatric surgery was 181 kg (398 pounds). Liposuction was performed along the posterior and medial aspects of her arms immediately before tissue undermining and excision. No liposuction was performed at the axilla. The scar was placed along the posteromedial aspect of the arm in an effort to make it less conspicuous. The patient had concerns about the constrictive band along the distal aspect of her left arm. One option to address this band was to perform a Z-plasty along the band; however, this option was not pursued, primarily because of the possibility of a scar in a more visible location.

This 70-year-old woman lost 52 kg (115 pounds) as a result of bariatric surgery. She presented 4 years after surgery at a weight of 61 kg (135 pounds); her highest weight before surgery was 113 kg (250 pounds). She had a relatively large amount of excess soft tissue despite moderate weight loss. She presented with concerns about her axillae, arms, and forearms. We performed liposuction along the posterior and medial aspect of her arms immediately before tissue undermining and excision. No liposuction was performed at the axillae. The scar was placed along the bicipital sulcus, our choice for scar placement at the time. Note that the scar continued onto the proximal forearm in an effort to address contour concerns in that area.

This 55-year-old man had lost 68 kg (150 pounds) as a result of bariatric surgery. He presented 2 years after surgery at a weight of 110 kg (242 pounds); his highest weight before bariatric surgery was 178 kg (392 pounds). As is typical of men, his arm contour deformity was primarily limited to the axillae and proximal half of the arms. Liposuction was performed along the posterior and medial aspect of his arms immediately before tissue undermining and excision. No liposuction was performed at the axillae. The scar was placed along the bicipital sulcus, our choice for scar placement at the time. Note that the scar does not extend to the medial epicondyle, reflecting the limited extent of his deformity.

Pertinent Anatomy

When considering the posteromedial approach to brachioplasty, it is essential that the surgeon identify several superficial anatomic landmarks for consistent scar placement. Important surface anatomy includes the anterior and posterior axillary folds, biceps and triceps muscles, medial epicondyle, medial bicipital furrow, and medial cubital sulcus. A posteromedial approach to brachioplasty in virtually all instances involves the axillary dome, the area between the anterior and posterior axillary folds. An incision in this region should remain superficial, involving only skin and a small amount of subcutaneous fat. Liposuction is not usually performed in this region. The superficial-lying intercostobrachial nerve is sometimes encountered and inadvertently cut, with resulting numbness along the proximal medial aspect of the arm. This condition is well tolerated by patients and rarely noted. Liposuction before dissection of the medial and posterior arm should provide an easily identifiable plane immediately deep to the superficial fascial system and superficial to the deep fascia of the arm. Along the entire arm and elbow, vital structures remain deep to the deep fascia and are unlikely to be injured.

Along the proximal two thirds of the medial and posterior aspects of the arm, lying superficial to the deep fascia, are the medial and posterior brachial cutaneous nerves and small superficial unnamed veins. The cephalic vein and anterior brachial cutaneous nerve should remain out of the field of sharp dissection. Prior liposuction and careful dissection should spare the medial and posterior cutaneous nerves. Injury to these nerves would result in corresponding numbness to these areas of the arm.

Along the distal third of the arm and in the elbow region, the basilic vein and medial antebrachial cutaneous nerve lie superficial to the deep fascia and are vulnerable to injury. Once again, liposuction before sharp dissection in this area is helpful in visualizing these more important structures.

Zones of adherence along the arm are limited primarily to the lateral arm and elbow region. The posteromedial approach does not involve sharp dissection along the lateral arm, and fat deposits in this area are not common. Liposuction along the medial and posterior arm addresses the fat deposits commonly encountered along the posterior elbow and facilitates sharp dissection along the medial elbow.

Preoperative Assessment

Candidates for brachioplasty should undergo thorough history-taking and physical examination. Photographs of the areas of concern are obtained. As for all post-bariatric patients, special attention should be directed toward the patient's weight history. Critical information includes the patient's height, current weight, and maximum weight. The time interval between their maximum and current weight and length of time at the current weight should be documented. If weight loss was achieved through bariatric surgery, the technique and when surgery was performed should be recorded. Other important weight-related information includes whether the individual is being followed by a bariatric surgeon, the date of the last visit, and whether supplemental medication has been prescribed and is being taken regularly. Problems potentially related to bariatric surgery should be explored, such as frequent vomiting, abdominal pain, weakness, light-headedness, and frequent bowel movements. For patients who have lost weight through lifestyle changes, the surgeon should determine how this was accomplished: through exercise, diet and exercise, and/or medication, and whether the patient is being supervised by a professional. Physical examination of a postbariatric brachioplasty candidate should be thorough, with particular attention to the upper body. Along with the degree of soft tissue excess present along the forearm, arm, and axilla, an assessment should be made of the breasts, flanks, and back. The fat content of all these areas should be noted. A standardized examination form is helpful. The examiner should note whether intertriginous dermatitis is present, potentially along the axilla. Lymphedema and/or the stigmata of lymphedema should be documented, as should the presence of arterial or vascular insufficiency. Existing scars, banding, and striae along the upper extremity should be documented.

Patient Goals

For some individuals following weight loss, the appearance of the arms is their primary or only concern. More often, however, the arms are one of many concerns. The average age in our postbariatric population is 39. Most of these patients are very active and eager to minimize time off from work and time away from family obligations. It is therefore quite common for a patient to express concerns about multiple areas of the body and to request that all areas be addressed as soon as possible. One of the most important components of patient assessment is determining in what order and with what other procedures a brachioplasty should be performed. The patient's goals should be carefully considered in formulating a plan. With regard to the arms, it is important to gain a clear understanding of the patient's tolerance for scars and of the degree of contour improvement he or she is expecting. A postbariatric patient anticipating an optimal result from a procedure with a scar limited to the proximal arm is likely to be disappointed.

PREOPERATIVE ASSESSMENT FOR BRACHIOPLASTY

Patient name _____ Date _____

ARM	Left:	Striae:	Yes	No				
		Skin excess:	None	Mild	Moderate	Severe		
		Lipodystrophy:	None	Mild	Moderate	Severe		
		Scars:	Yes	No				
		Constrictive band	Yes	No				
	Right:	Striae:	Yes	No				
		Skin excess:	None	Mild	Moderate	Severe		
		Lipodystrophy:	None	Mild	Moderate	Severe		
		Scars:	Yes	No				
		Constrictive band	Yes	No				
AXILLA / FLANK	Left:	Lipodystrophy:	None	Mild	Moderate	Severe		
	Right:		None	Mild	Moderate	Severe		
	Left:	Skin excess:	None	Mild	Moderate	Severe		
	Right:		None	Mild	Moderate	Severe		
BREAST	Current breast size:		Desired breast size:					
	Excess grams of breast tissue:		Left	Right				
	Diameter of nipple-areola complex:		Left	Right				
	Distance from sternal notch to nipple (normal 23-25 cm):		Left	Right				
	Distance from inframammary fold to nipple (normal 10-12 cm):		Left	Right				
	Distance from midline to nipple (normal 10-12 cm):		Left	Right				
	Scars:	Left:	Biopsy	Inverted T	Vertical	Periareolar	Inframammary	Axillary
		Right:	Biopsy	Inverted T	Vertical	Periareolar	Inframammary	Axillary
	Breast ptosis:	Left:	None	Grade I	Grade II	Grade III	Pseudoptosis	
		Right:	Biopsy	Inverted T	Vertical	Periareolar	Inframammary	
	Lymphadenopathy:	Left:	None	Axillary	Supraclavicular			
		Right:	None	Axillary	Supraclavicular			
	Palpable mass:	Left:	Yes	No				
		Right:	Yes	No				
	Nipple discharge:	Left:	Yes	No				
		Right:	Yes	No				
	Shoulder grooving:	Left:	Yes	No				
		Right:	Yes	No				
	Baker capsular contracture:	Left:	None	Mild	Moderate	Severe		
		Right:	None	Mild	Moderate	Severe		
	Gynecomastia:	Left:	Type I	II	III	IV	Hypertrophy:	A B C
		Right:	Type I	II	III	IV	Hypertrophy:	A B C
Tuberous breast:	Left:	None	Mild	Moderate	Severe			
	Right:	None	Mild	Moderate	Severe			
ABDOMEN	Striae:	Yes	No					
	Scars:	None	Midline	Epigastric	Hypogastric	Left subcostal		
		Right subcostal	Chevron	Left paramedian	Right paramedian			
		Left inguinal	Right inguinal					
	Hernia:	None	Ventral	Incisional	Umbilical	Left inguinal	Right inguinal	
	Skin excess:	Left:	None	Mild	Moderate	Severe		
		Right:	None	Mild	Moderate	Severe		
	Lipodystrophy:	Left:	None	Mild	Moderate	Severe		
		Right:	None	Mild	Moderate	Severe		
	Fascial laxity:	Left:	None	Mild	Moderate	Severe		
		Right:	None	Mild	Moderate	Severe		
	Intertriginous dermatitis:	Yes	No					

Preoperative Planning

The information gathered from the patient history and physical examination is instrumental in formulating a preliminary plan. For patients expressing concerns only about their arms, the plan is clear. For these patients, it is important to clarify the importance of addressing the axilla in rejuvenating the arm (see pp. 2821-2822). Most patients following massive weight loss express concerns about more than just their arms; usually the breasts, flanks, back, abdomen, thighs, and buttocks are sources of dissatisfaction as well. Multiple options are available to the plastic surgeon.

We prefer to perform a body lift first as a single procedure, then follow with a combination mastopexy/lateral thoracoplasty/brachioplasty a minimum of 3 months later. A medial thigh lift, if necessary, would be performed at least 3 months after that. Our rationale for this sequence and combination of procedures derives from the observation that the body-lift procedure greatly affects the rolls frequently present along the upper and lower back (see p. 2835). In the vast majority of patients, any remaining rolls along the back and flanks following a body lift can then be addressed by the combination mastopexy/lateral thoracoplasty/brachioplasty.

This 30-year-old woman had a 59 kg (130-pound) weight loss. She is shown 10 months after a body lift and 4 months after a medial thighplasty. Improvement to the back contour is evident.

Although the upper body procedures may be performed before the body lift, it is often difficult to accurately estimate the appropriate amount of tissue to be excised in the lateral thoracic region. The vast majority of postbariatric patients are candidates for a body lift.

Before an individual can be considered for any procedure, certain criteria must be met and issues addressed. The patient should be at a stable weight for several months; this will vary, depending on the bariatric procedure. Operating during a period of

active weight loss may result in early recurrence of soft tissue laxity, and from a safety perspective, the patient's nutritional and metabolic status is unlikely to be optimal. Patients with symptoms that suggest problems related to bariatric surgery should be evaluated by their surgeon, and patients are advised to maintain the supplemental regimen prescribed by their bariatric surgeon. Individuals with a history of major or acute mental illness are asked to undergo evaluation by an appropriate health professional. Individuals with a history of tobacco consumption are urged to stop as soon as possible. The risks of tobacco use are clearly established in the literature, and patient education includes explanations of potential wound-healing problems and thromboembolic disease. We ask patients who are on medications as part of their weight-loss protocol to stop taking them. All patients are referred for medical clearance. Although weight loss dramatically improves the health of morbidly obese individuals, not all conditions are eliminated. A careful medical evaluation of their health is imperative.

After discussing a possible plan with the patient, we review several topics. Many individuals are eager to lose more weight before surgery, feeling that their surgery will be safer and that more skin can be removed if they are at a lower weight. We think that most people whose weight is stable at the time of consultation are at the weight they are most likely to maintain over the long term. Many weight-stable postbariatric patients can lose additional weight for relatively brief periods of time—several months, perhaps a year—but long-term sustained additional weight loss is difficult to achieve. Weight loss over a short period of time can lead to several undesirable outcomes. First, the individual may become nutritionally and metabolically unbalanced just at the time contouring surgery is to be performed. Second, weight gain in the future will in most instances diminish the aesthetic results of a procedure. We advise patients to eat a balanced diet and maintain a stable weight. We also explain that a certain amount of excess soft tissue will be removed during surgery. Their new weight after surgery should be their current weight minus the weight of the tissue removed. A 3-month postoperative weight similar to their weight at consultation suggests a significant weight gain. We also explain that the long-term results of this surgery are best maintained by weight stability, minimizing exposure to sun (ultraviolet light), and no tobacco consumption.

Laboratory Tests

The patient's history can often suggest the presence of problems; however, a thorough laboratory workup is essential to identify existing deficiencies or abnormalities. It is not unusual for menstruating women to have few if any symptoms despite having severe anemia as a result of bariatric surgery. Along with a complete blood cell count and other studies, our routine includes a complete metabolic panel. Ab-

normal laboratory values are acted on as they are made available. Individuals found to be malnourished (regarded as a total protein level less than 6 g/dl and/or albumin less than 3 g/dl) may be referred to their bariatric surgeon for reevaluation and possible nutritional supplementation. Those findings may be corroborated by the presence of edema on physical examination. Protein-depleted patients may have difficulty with wound healing. Severely anemic patients (those with a hemoglobin level less than 10 g/dl) are referred to their primary physician and/or a hematologist. Patients with a hemoglobin level above 10 g/dl are advised to continue taking iron, folate, and B₁₂ supplementation and to have their blood cell count repeated in 1 week. We prefer that patients have a hemoglobin level above 12 g/dl before surgery. Patients are advised of the possible need for a blood transfusion. We do not have patients bank their own blood: in most institutions, blood can only be given within 1 month of surgery, and 1 month may not be adequate time for an anemic patient to replenish his or her blood levels.

Preoperative Visit

At the preoperative visit, usually 2 weeks before surgery, we review the planned surgical procedure in detail with the patient, as well as the potential complications. Any requested consultations and recommendations are discussed at this time. Another critical function of the preoperative visit is to review the photographs taken at the first consultation. Patients rarely have a completely accurate sense of their deformities. Key elements of this discussion are to highlight existing asymmetries, the presence of constrictive bands (which in many cases cannot be completely corrected), review the extent of their deformities, and to explain the degree to which the planned procedure or procedures will address these deformities. We prefer not to morph patient images on the computer but rather to show preoperative and postoperative examples of individuals with similar body types who have had the same procedure. Perhaps more than any other postbariatric body-contouring procedure, candidates for brachioplasty must have a very clear understanding of the scar involved. The process of scar maturation must be discussed, as should the potential risks for hypertrophic and hyperpigmented scars. Failure to discuss the full spectrum of scar quality can lead to a disappointed patient despite an excellent contour result. Restrictions and recovery guidelines are reviewed. Patients often have the sense that recovery from surgery should involve significant bed rest; instead, we emphasize the importance of early and frequent ambulation. Medications that should be avoided before surgery are reviewed: those that increase the risk for bleeding, such as aspirin and NSAIDs, and medications that increase the risk for deep venous thrombosis (DVT), such as birth control pills or hormone replacement therapy. Patients are advised not to take either for 2 weeks before or after surgery. We conclude the consultation with an explanation of the plan for DVT prophylaxis.

Restrictions and Recovery Guidelines

1. Dressings are removed 2 days postoperatively. Showering is permitted at this time. You should keep your underarms dry at all times when not showering.
2. No special garments are required.
3. Avoid perspiring excessively for 2 weeks.
4. Deodorants or antiperspirants may be applied 2 weeks after surgery. (Many patients report that they have no need or less need to apply these products, because in most cases a significant number of sebaceous glands and hair follicles have been removed.)
5. Avoid lifting your arms (not the forearms) above shoulder level for 2 weeks after surgery (the forearms and hands may be used for grooming).
6. Vigorous activities involving the lower body may be resumed 2 weeks after surgery. Vigorous activities of the upper body, including the arms, may be resumed 6 weeks after surgery.

Thromboembolic Disease Prophylaxis

Thromboembolic disease has been very rare in our brachioplasty series. All patients undergoing brachioplasty have activated lower extremity sequential compression devices in place before surgery, during surgery, and until they are regularly ambulating. After surgery, patients are encouraged to walk shortly after the procedure. Patients with a BMI above 32 are given 5000 units of heparin subcutaneously before surgery. Individuals with risk factors other than obesity are treated on a case-by-case basis. Thromboembolic disease prophylaxis for patients undergoing brachioplasty and additional procedures, particularly abdominoplasty, is outside the scope of this chapter but is discussed in detail in Chapter 79.

PERIOPERATIVE MANAGEMENT

Preoperative Planning

The goal of our technique is for the scar to lie along the posterior medial arm, approximately at the level of the triceps muscle. At the axilla, the scar should lie within the axillary dome.

Marking begins with the patient standing and the arm extended perpendicular to the body. A line is drawn along the lateral inferior border of the pectoralis major muscle from point A, the superior portion of the axillary dome to point B, the inferior portion of the dome. A point C is found, usually at the level of the triceps muscle that can be advanced easily to a point D at the most superior portion of the axillary dome. The points at A, B, and C are connected to complete the ellipse at the axilla. These steps determine the soft tissue excess to be excised from the axillary dome. A dashed line is then drawn from the medial epicondyle, point E, to the lateral aspect of the axillary dome over the triceps muscle, point F. In heavier individuals, the posterior portion of the arm may need to be grasped to determine the location of the triceps muscle. Finally, area G above the dashed line E-F is identified, corresponding to the region of maximum soft tissue excess on the posterior aspect of the arm. Moderate downward traction is placed on the area using multiple digits, typically the index, long, ring, and small fingers, to identify level H, which descends to the height of point E, or the medial epicondyle. A line is then drawn from point E through H and onto the lateral aspect of the ellipse, point I. The line from E through point H should mirror the corresponding soft tissue excess of the posterior arm in that region. Typically the line rises gradually over the distal arm and rises more as it reaches the proximal arm.

Operative Technique

80-1 Brachioplasty

Draping for bilateral brachioplasty, performed with lateral thoracoplasty and mastopexy

Sterile drapes are placed on the operative table and arm boards. With the patient supine, a sequential compression device is placed on one leg and a blood pressure cuff on the other. An intravenous catheter is placed in the dorsal aspect of the hand or wrist. Intravenous antibiotics are given, typically a first-generation cephalosporin. A pulse oximeter sensor is placed on the ear. Following administration of general anesthesia, often with a laryngeal mask, the forearm, arm, axilla, flank, and chest are prepared with povidone-iodine solution (Betadine). A sterile towel is wrapped around each hand and proximal forearm and secured to itself and the patient with staples. An ether drape is stapled to the patient along the upper chest and over the midclavicular portion of the shoulders. Sterile drapes are placed over the patient's body from the lower chest and inferiorly.

The previously made markings along the axilla, points *A* to *B*, up to *C*, and back to *A* are scored with a knife blade. Similarly, the line from *E* through *H* and onto the lateral limb of the axillary ellipse, point *I*, is scored. Beginning with the right arm and using a No. 15 blade, the surgeon makes four stab wounds: along the medial forearm, just distal to the medial epicondyle, the proximal and midposterior arm, and the distal lateral arm. Through these stab wounds tumescent fluid (1 L of saline solution, 1 ml of 1:1,000 epinephrine, 50 ml of 1% lidocaine) is injected into the subcutaneous tissues of the medial and posterior arm. If fatty deposits are to be addressed along the anterior and lateral arm, fluid should be injected into these areas as well. Our preference is to inject at a 1:1 ratio, fluid injected equaling effluent removed. Excessive fluid injection may compromise control over the excision. While the tumescent fluid is setting, the ellipse at the axilla is excised. Only a small amount of subcutaneous fat is removed with the skin to avoid any deeper structures.

Liposuction is then performed with a 3 to 4 mm cannula, beginning through the stab wound along the proximal medial forearm. By this approach, the medial arm is suctioned with particular attention to the distal area, where the skin is more firmly adherent to the underlying fascia. The arm is typically resting on the arm board during this maneuver. Suction is then performed along the posterior and posterolateral arm through the stab wound along the distal lateral arm. The surgeon is standing and the forearm is elevated off the arm board by an assistant. Finally, the entire posterior arm is liposuctioned through the posterior stab wounds. The arm is rotated medially over the patient's chest. With the arm resting on the arm board, the surgeon incises the skin from points *E* to *I*. The subcutaneous tissues are divided to reach the honeycomb-appearing plane produced by the liposuction. In this plane, dissection is readily performed to the posterolateral aspect of the arm.

The appearance of the subcutaneous tissues after liposuction to the medial and posterior arm is shown. The plane of dissection is readily visible.

The supporting ligaments to the skin in the region of the elbow are thicker and slightly more difficult to divide. With the dissection complete, a towel clamp or an Adair clamp is used to approximate the lateral skin edge of the axillary ellipse, point *I*, to a point directly across the ellipse along the medial axillary skin edge. Towel clamps are then used to approximate the lateral skin edge at a point beginning below *E* to point *I*, already approximated. The correct point whether *C* or a point between *C* and *B*, is the point that creates the desired contour of the proximal arm but avoids excessive tension. Once the desired point is found, the skin edges of the axillary ellipse have been approximated. Attention is then directed toward the arm. Towel clips are placed along the upper divided skin edge, *E* to *I*.

Beginning in the region of greatest tissue excess of the arm, typically slightly proximal to the mid-arm, a Pitanguy long skin demarcator is secured to a towel clip. The surgeon and assistant then apply upward traction on the entire lower skin flap edge. Advancement of the demarcator posteriorly toward the lower flap will cause it to glide posteriorly for 1 cm or more before stopping. The lower flap is drawn into the jaws of the demarcator under moderate tension. Once mild resistance is reached, the lower flap is released by approximately 1 cm. This point is then marked.

The same technique is repeated along the arm three or four times to develop an outline of the flap to be excised. The dots are connected and the flap excised. Hemostasis is carefully restored. No drain is placed. Towel clamps are used to approximate the flap edges along the axilla and arm. At the axilla, 2-0 Vicryl interrupted sutures are used to approximate the superficial fascial system and deep dermis, approximately 0.5 cm from the flap edge. Incorporated in this approximation is a superficial bite of the deeper tissues to help eliminate dead space. A 3-0 Monocryl intracuticular suture is then placed. A similar closure with 2-0 Vicryl and 3-0 Monocryl is used along the arm; however, the deeper tissues are not incorporated in the closure. ABD pads are placed on the wounds of the axilla and arm, followed by a loosely applied elastic wrap to the arm. To support the dressings at the axilla, an upper pole breast binder is placed, or if breast surgery is being performed concomitantly, a bra is placed.

In our practice, the lateral thoracic region is often addressed in combination with a brachioplasty and mastopexy. The sequence of procedures in these cases is for the mastopexy to be performed first. From the lateral extent of the inframammary wound closure, the tailor-tacking technique is then used to assess the excess skin and soft tissue along the lateral thoracic region and to the dome of the axilla. Next the excess skin and a small amount of subcutaneous fat from the lateral thoracic region and axilla are removed. The arm portion of the brachioplasty procedure can then begin as described previously from the step in which liposuction is performed. The remainder of the procedure is the same, except for the final wound closure, which extends inferiorly from the axilla to the lateral thoracic region and terminates at the lateral extent of the mastopexy inframammary wound closure. If large areas of skin and soft tissue have been removed from the lateral thoracic region, the dermal sutures can be placed to incorporate a superficial bite of the tissues at the base of the wound, or a drain can be left in place for several days. These efforts may diminish the likelihood of a seroma or persistent fluid drainage from the axilla.

The proximal forearm, in addition to the arm, may be a concern for some patients, particularly women in their fifth decade and beyond. Management of the proximal forearm begins with the routine brachioplasty, as described previously, up to the point just before the final intracuticular layer of 3-0 Monocryl is placed. With the 2-0 Vicryl suture in place, the tailor-tacking technique is used to assess the excess skin and soft tissue along the proximal forearm beyond the medial epicondyle. The skin and a small amount of subcutaneous fat from the pattern created along the proximal medial forearm are removed. The final closure begins with 2-0 Vicryl in the forearm, followed by 3-0 Monocryl along the forearm, arm, and axilla.

Postoperative Care

Ambulation is encouraged as soon as possible after surgery. Brachioplasty is nearly always performed in an ambulatory setting, particularly if it is the only operation being performed. The patient is usually discharged several hours after the procedure. Dressings are removed 2 days later, and the patient is then allowed to shower.

Patients are encouraged to take narcotic analgesics as needed but to taper them as soon as possible. They are reminded to avoid elevating their arms above shoulder level. Routine follow-up visits are planned for 1 week, 6 weeks, 3 months, 6 months, and yearly thereafter. Images are usually taken at the 3-month follow-up.

Problems and Complications

Major complications are very few following brachioplasty. In our review of 350 brachioplasty cases (700 arms), skin dehiscence was the most frequent complication at 25%. None of the instances of dehiscence occurred acutely; that is, within the first 24 to 48 hours after the procedure. Rather, dehiscence began to become evident approximately 2 weeks after the procedure. Nearly all (95%) instances occurred at the intersection of the closure of the axillary dome and the arm.

As in many skin flaps that are triangular, the tip of the flap has a compromised blood supply. In the days after the procedure, the tip can become increasingly ischemic, taking on a dusky appearance, and at 2 weeks actual skin separation occurs. Most skin dehiscences (over 90%) were less than 2 cm in size.

Avoiding this complication is challenging, because some form of Z-plasty must be used for the closure to extend from the axilla to the arm to prevent scar contracture. Although advising the patient to limit extension of the arm may be helpful, it is unlikely to entirely prevent this problem. Dehiscences are treated with dressing changes. In some instances, hypergranulation tissue may arise in the area of skin dehiscence. Application of nitrate is very effective.

Seromas are the second most frequent problem (10%). Approximately 90% occur along the distal medial third of the arm, immediately beneath the scar. Most become evident at about 3 weeks postoperatively and range in diameter from 1 to 4 cm. Initially we manage them by needle aspiration; unfortunately, this technique has a very high recurrence rate.

Marsupialization, which consists of incising the skin over the seroma, draining the seroma, and suturing the seroma cavity to the skin, is 100% effective but results in a scar that may be wider than the adjoining scar and can prolong wound healing. Currently we prefer to drain the seroma through the scar and place a secured Penrose type of drain into the seroma cavity. This technique has also proved very effective. Patients receive antibiotics while the Penrose drain is in place.

Infections have had been very infrequent, as have bleeding and hematomas. Complaints of dysesthesia beyond 3 months have been few, and rare beyond 6 months. Skin necrosis has also been very infrequent despite liposuction being performed in virtually all cases.

We have had only one documented instance of DVT in a patient who underwent brachioplasty. The patient presented with a palpable cord extending from the forearm to the arm. There have been no instances of pulmonary embolism.

Complication Rates Associated With Brachioplasty (N = 350 cases; 700 arms)

Complication	Percentage
Skin dehiscence	25.0
Seroma	10.0
Infection	2.6
Hematoma	0.6
Skin necrosis	0.6
Deep venous thrombosis	0.3
Pulmonary embolism	0.0

Results

The following cases have been selected to represent the broad range of postbariatric patients following brachioplasty.

This 25-year-old woman presented 4 years after bariatric surgery that resulted in a weight loss of 58 kg (128 pounds). Her current weight was 62 kg (137 pounds) with a BMI of 25. Her highest weight had been 120 kg (265 pounds) with a BMI of 48. She is seen 6 months after brachioplasty with concomitant liposuction and postero-medial scar placement. Note the improvement of the axilla, a critical component of an effective brachioplasty. Scars placed in this position are less noticeable than those along the bicipital sulcus.

This patient was a good candidate for brachioplasty. She was 31 years old and had undergone bariatric surgery 4 years earlier. As a result, she had lost 92 kg (203 pounds). Her current weight was 89 kg (195 pounds) with a BMI of 35. The highest weight and BMI she ever reached were 181 kg (398 pounds) and 71, respectively. She is seen 3 months after brachioplasty and concomitant liposuction, with scar placement along the posteromedial arm. Although the results are dramatic, the aesthetic level achieved is not the same as for the preceding ideal candidate. Note the constrictive band along the left arm that could not be eliminated.

This 70-year-old woman presented 4 years after bariatric surgery that had produced a weight loss of 52 kg (115 pounds). Her current weight was 61 kg (135 pounds) with a BMI of 25. Her highest weight had been 114 kg (250 pounds) with a BMI of 46. She is seen 6 months after brachioplasty and concomitant liposuction, with scar placement at the bicipital sulcus. Note that her deformity extends from the axilla and arm to the proximal forearm; this is typical of older women. In addition, her deformity is greater than might be expected from her degree of weight loss.

This 55-year-old man was initially seen when he requested brachioplasty 2 years after undergoing bariatric surgery through which he had lost 58 kg (128 pounds). His weight at the first visit was 109 kg (240 pounds) with a BMI of 35. His highest weight had been 177 kg (391 pounds) with a BMI of 58. He is seen 3 months after brachioplasty and concomitant liposuction, with scar placement along the bicipital sulcus. As is typical of men, his deformity was primarily limited to the axilla and proximal half of the arm. Although the erythema of his scar is quite typical for this postoperative period, this degree of scar visibility influenced our decision to place scars slightly more posterior along the medial aspect of the arm.

Concluding Thoughts

Increasing numbers of individuals are requesting arm contouring after massive weight loss. It is important that plastic surgeons have a safe, effective, and reliable technique to address upper extremity concerns. Careful preoperative evaluation with particular attention to weight history is the first step in creating the appropriate plan for each individual. The preoperative evaluation should include a clear understanding of patient expectations and their comfort level with scars. Examination of the patient should make note of the extent of the arm deformity, but also of surrounding structures such as the forearm, axilla and lateral thoracic region. Once a patient has been evaluated and a plan formulated, the brachioplasty procedure should proceed

in an organized, step-wise fashion. The technique described in this chapter has been performed hundreds of times on a wide array of postbariatric patients. The outcomes have been carefully evaluated and are associated with few significant complications and a high level of patient satisfaction. The goal of the technique is to restore normal contour to the arm and adjacent structures, with scars placed in the least noticeable locations. To achieve this in patients of varying BMIs, concomitant liposuction plays an essential role. Liposuction helps to create a safe plane for dissection and remove excess fat, making it possible to safely remove more excess soft tissue. Brachioplasty can be a consistently rewarding experience for both the plastic surgeon and postbariatric patient when careful attention is placed on preoperative evaluation and screening, scar placement, the treatment of the arm and adjoining structures, and the appropriate use of liposuction.

Clinical Caveats

Careful patient selection is critical for optimizing the outcome from brachioplasty surgery.

In postbariatric patients, the arm contour deformity must be evaluated as a part of the upper body and not as an isolated area.

Candidates for brachioplasty must have a clear understanding of scar visibility.

Upper extremity and upper body asymmetries, including the presence of constrictive bands, should be highlighted and discussed with patients before surgery.

Preoperative marking should be performed consistently, particularly with regard to patient position.

The surgical plan and sequence of steps should be determined before the procedure.

The excisional component of brachioplasty must be performed in a methodical and detailed fashion.

Liposuction should be considered for most postbariatric brachioplasty patients.

Annotated Bibliography

Abramson DL. Minibrachioplasty: minimizing scars while maximizing results. *Plast Reconstr Surg* 114:1631-1634; discussion 1635-1637, 2004.

A short-scar brachioplasty or minibrachioplasty technique is described that limits the scar to the axilla and proximal arm. Eight patients were treated with the technique. Brachioplasty techniques with scars limited to the proximal arm are likely to have a limited scope of utility in massive-weight-loss patients.

Gusenoff J, Coon D, Rubin JP. Brachioplasty and concomitant procedures after massive weight loss: a statistical analysis from a prospective registry. *Plast Reconstr Surg* 122:595-603, 2008.

The authors analyze data from a prospective registry of massive-weight-loss patients who underwent brachioplasty alone or with concomitant operations to identify statistically significant complications (a total of 101 cases). Outcome measures included operative time, time since the gastric bypass, need for revision, arm liposuction, and complications such as seroma, dehiscence, hematoma, infection, and nerve injury. Patients with a greater change in BMI had a higher likelihood of wound infection. Longer operative time was associated with increased rates of surgical complications at the operative site. There was a trend toward increased complications when arm liposuction was combined with brachioplasty.

Hallock GG, Altobelli JA. Simultaneous brachioplasty, thoracoplasty and mammoplasty. *Aesthetic Plast Surg* 9:233-235, 1985.

A technique for combining brachioplasty with mammoplasty and lateral thoracoplasty is described. The majority of women following massive weight loss can benefit from this combination. Failure to treat the lateral thoracic region may lead to a suboptimal result at the breasts or arms.

Lockwood T. Brachioplasty with superficial fascial system suspension. *Plast Reconstr Surg* 96:912-920, 1995.

Anatomic studies of five cases were reported by the author; these reveal that the posteromedial soft tissue of the arm in youth is firmly suspended to the clavipectoral periosteum by means of the clavipectoral and axillary fasciae. Loosening of these structures leads to ptosis of the posteromedial arm. On the basis of this anatomic concept, the brachioplasty technique proposed provides anchoring of the arm flap to the axillary fascia and repair of the superficial fascial system to reduce the risk of scar widening or migration and unnatural arm contours.

Pascal JP, Le Louarn C. Brachioplasty. *Aesthetic Plast Surg* 29:423-429; discussion 430, 2005.

A technique for brachioplasty is described in which the scar is placed along the posteromedial arm and concomitant liposuction is used to help preserve both deep and superficial lymphatics, reduce damage to blood vessels and nerves, reduce volume, and allow better tissue mobilization. The series included 21 patients.

CHAPTER 81

Back and Lateral Fold Contouring

DIRK F. RICHTER, ALEXANDER STOFF

With the steadily rising global rate of obesity—according to the World Health Organization, 300 million people worldwide are obese—there has been a substantial increase in the number of bariatric operations since the early 1960s. Because massive weight loss usually results in a significant and disfiguring excess of skin and soft tissue, there has been an increasing demand among patients for body-contouring procedures to complete the desired results. Many operative techniques have been developed and refined to a high standard, increasing the popularity and effectiveness of these procedures.

In the past, operations such as abdominoplasties and medial thigh and gluteal lifts were performed as multistage procedures for patients after massive weight loss. These have given way to modern, holistic concepts of treatment, such as circumferential lifting and full lower body lifts, the current benchmark procedures for postbariatric patients.

However, to date, treatment of the lateral and dorsal thoracic regions has not been as satisfactory, as indicated by surgical experience and the absence of reports of good results in the literature. The thick skin, fibrous soft tissue with lobulated fat, and poor retraction capability of this region have limited the success of treatment. Furthermore, scarring in the lateral and dorsal thoracic regions cannot be adequately hidden by underwear, especially in male patients; because of the thickness and quality of the skin, the scars in this region are usually significant and remain visible. In addition, scars are difficult to place in the natural, relaxed skin-tension lines. Because of these difficulties, minimally invasive, scar-reducing techniques such as liposuction are usually preferred, although the problem of poor skin retraction has remained insurmountable. Thus the results of liposuction-only treatments are disappointing, especially in patients after massive weight loss, primarily because of insufficient skin retraction.

To address these problems, we have developed a new method for treatment of the back, particularly the lateral and dorsal thorax, in massive-weight-loss patients. This technique combines surgical excision of skin redundancy with preliminary liposuction. The *upper lateral thoracic lift* (ULTL) is an alternative approach for eliminating skin excess in this region. It can be performed alone or as an integral part of a combined technique with upper body lift procedures.

Indications and Contraindications

The choice of technique must be individualized, based on the patient's preoperative characteristics. The importance of the individual's psychological attitude cannot be overstated, particularly in regard to his or her acceptance of the visible scars associ-

ated with this procedure. Fortunately, massive-weight-loss patients usually have a high tolerance for scar length and visibility.

In general, if there is skin and soft tissue excess in the form of local folds in the dorsal and lateral thorax, an excisional procedure will be necessary to correct the redundancy. Local liposuction can be worthwhile in cases of local soft tissue excess if there are no skin folds. The surgeon must assess the entire back preoperatively to determine the amount of skin elasticity present so that the areas of skin with the worst retraction potential can be distributed across a larger body surface, which will promote more effective skin retraction.

Patient Profiles

The ideal candidate for an excisional lifting operation is a psychologically prepared individual with significant skin and soft tissue excess with ptotic skin rolls and fold development. A BMI of 32 is the generally accepted upper limit for lifting operations to achieve good results with an acceptable complication rate. If patients are still too obese, their results will be poor and scarring unacceptable. Patients who tend to develop hypertrophic scars should not be considered for this operation, because the back is prone to noticeable scars and development of keloids.

Suitable candidates for liposuction have skin that is neither too thin nor too thick, with an obvious excess of subcutaneous fat. Using a technique that combines superficial and deep liposuction of the area, the surgeon can achieve good skin retraction; however, there is a risk of skin dimpling. If dimples occur, ultrasound-assisted liposuction may be used to ameliorate this problem (Jewell).

Pertinent Anatomy

The entire back and lateral thoracic areas have a central conjoined zone over the vertebral column. When a person gains weight, this zone remains nearly unchanged; there are few fat cells there that can hypertrophy because of the connections between skin and fascia. More laterally, the tissue is thicker and heavier, and it gradually collapses back on itself, like a roman shade. Thus multiple rolls are formed, as previously described by Strauch and colleagues.

A classification for these back rolls includes an upper breast roll, followed by a lower scapular roll and a deeper lower chest/thoracic roll. An analogous classification is made for the iliac area hip rolls. The wrinkles can be seen individually as well as collectively.

In our patient population we have found strongly asymmetrical patterns, such as one roll on one side and four rolls on the other side. For this reason the surgeon has to evaluate each patient carefully for the presence of scoliosis, hip problems, or leg differences. It is thought that ligamentous structures of different strengths are responsible for the development of these asymmetrical rolls. A pathohistologic study that correlates the different types of collagen to the clinical outcome is currently under analysis.

Left: Cutaneous vascular territories are shown in different colors in this cadaver angiogram to facilitate identification: CSA, Circumflex scapular artery; DCIA, deep circumflex iliac artery; DPIA, dorsal branches of posterior intercostal arteries; IGA, inferior gluteal artery; IPA, internal pudental artery; LA, lumbar arteries; LCFA, lateral circumflex femoral artery; LPIA, lateral branches of posterior intercostal arteries; LSA, lateral sacral arteries; MCFA, medial circumflex femoral artery; SCIA, superficial circumflex iliac artery; SGA, superior gluteal artery; TCT, thyrocervical trunk; TDA, thoracodorsal artery.

The back is perfused primarily by the perforating vessels of the latissimus dorsi. The area around the sacrum is supplied by numerous small arteries with no single main vessel, making the area a danger zone for development of decubitus ulcers and circulatory disturbance after a lifting procedure. New data must be evaluated with regard to lymphatic clearance, since surgical interventions in these areas (such as a latissimus dorsi flap, belt lipectomy, or extensive liposuction) present a high risk for seroma formation.

Preoperative Assessment

A detailed medical history is taken and the patient's BMI is determined during the initial consultation and physical examination. All local physical conditions must be assessed. It is important to ensure that the patient is psychologically prepared to accept the significant scars associated with these procedures. This is particularly criti-

cal for treatment of the upper folds of the back, because these often leave visible scars that are not easy to hide. Careful planning and explicit discussion with the patient are essential.

The quality and thickness of the skin folds are of particular interest and should be measured. The degree of mobility and the elasticity of the tethered areas provide helpful information for planning an effective operation.

The patient is evaluated with his or her arms maximally elevated and lowered. We recommend that a standard photographic series be obtained showing the full range of motion of the arms from 0 to 180 degrees to clarify and document the mobility of the skin folds and the overlying tissue.

The individual breast, scapular, and lower thoracic rolls should be measured with skin calipers. If liposuction-only treatment is indicated for a patient with one roll or even a certain degree of generalized obesity of the back or hip, it is essential to evaluate the thickness of the fat layer for preoperative planning. If liposuction is to be done, high-resolution ultrasonography may be helpful to define the thickness of the skin and fat layers to enhance planning.

We generally advise patients to refrain from taking any nonessential medications for 14 days before the operation, particularly those that could interfere with coagulation or lead to increased bleeding.

Preoperative Planning

Primarily we attempt to combine an upper arm lift with a breast lift and an integrated ULTL. This technique treats the upper part of the body as one unit. As a guide, we say that the two upper folds often can be treated by various surgical options or the lower body lift (LBL) alone (because this lift exerts such an influence on the entire back), whereas the two lower folds can only be effectively treated by using an LBL or a belt lipectomy.

When planning an LBL, it is important to remember the principle that *force equals counterforce*, so approximately one quarter of the soft tissue should be excised from the cranial side, with approximately three quarters removed from the caudal side.

However, we agree with the majority of surgeons that direct undermining of the back, especially in the sacral area, should be avoided. Aly excises the lower thoracic fold using a slightly higher incision line with the belt lipectomy. Thus approximately half of the lower thoracic fold can be resected, whereas the other half can be tightened by pulling downward.

Classification

The Pittsburgh Rating Scale has proved helpful for selecting the best operative approach. Overall, we agree with the general recommendations for treatment in this classification system; however, we have found a greater indication for the combined technique of liposuction and excisional procedures of the back.

The Pittsburgh Rating Scale*

Area	Scale	Preferred Procedure
Arms	0 Normal	None
	1 Adiposity with good skin tone	UAL and/or SAL
	2 Loose, hanging skin without severe adiposity	Brachioplasty
	3 Loose, hanging skin with severe adiposity	Brachioplasty $\pm$ UAL and/or SAL
Breasts	0 Normal	None
	1 Ptosis grade I/II or severe macromastia	Traditional mastopexy, reduction, or augmentation techniques
	2 Ptosis grade III or moderate volume loss or constricted breast	Traditional mastopexy $\pm$ augmentation
	3 Severe lateral roll and/or severe volume loss with loose skin	Parenchymal reshaping techniques with dermal suspension, consider autoaugmentation
Back	0 Normal	None
	1 Single fat roll or adiposity	UAL and/or SAL
	2 Multiple skin and fat rolls	Excisional lifting procedures
	3 Ptosis of rolls	Excisional lifting procedures
Abdomen	0 Normal	None
	1 Redundant skin with rhytids or moderate adiposity without overhang	Miniabdominoplasty, UAL and/or SAL
	2 Overhanging pannus	Full abdominoplasty
	3 Multiple rolls or epigastric fullness	Modified abdominoplasty techniques, including fleur-de-lis and/or upper body lift
Flank	0 Normal	None
	1 Adiposity	UAL and/or SAL
	2 Rolls	UAL and/or SAL
	3 Ptosis of rolls	Excisional lifting procedures
Buttocks	0 Normal	None
	1 Mild to moderate adiposity and/or mild to moderate cellulite	UAL and/or SAL
	2 Severe adiposity and/or severe cellulite	UAL and/or SAL $\pm$ excisional lifting procedure
	3 Skin folds	Excisional lifting procedure
Mons	0 Normal	None
	1 Excessive adiposity	UAL and/or SAL
	2 Ptosis	Monsplasty
	3 Significant overhang below symphysis	Monsplasty
Hips/lateral thighs	0 Normal	None
	1 Mild to moderate adiposity and/or mild to moderate cellulite	UAL and/or SAL
	2 Severe adiposity and/or severe cellulite	UAL and/or SAL $\pm$ excisional lifting procedure
	3 Skin folds	Excisional lifting procedure
Medial thighs	0 Normal	None
	1 Excessive adiposity	UAL and/or SAL $\pm$ excisional lifting procedure
	2 Severe adiposity and/or severe cellulite	UAL and/or SAL $\pm$ excisional lifting procedure
	3 Skin folds	Excisional lifting procedure
Lower thighs/knees	0 Normal	None
	1 Adiposity	UAL and/or SAL $\pm$ excisional lifting procedure
	2 Severe adiposity	UAL and/or SAL $\pm$ excisional lifting procedure
	3 Skin folds	Excisional lifting procedure

*Ten regions are assessed on a scale of 0 to 3. The presence of specific deformities determines the score. For each rating, the indicated surgical procedures are outlined. The procedures may be performed alone or in combination.

SAL, Suction-assisted lipectomy; UAL, ultrasound-assisted lipectomy.

PITTSBURGH RATING SCALE

0 (Normal)

1

2

3

It is important to start the planning with the LBL operation as the core part of the plan, because this operation exerts such a significant influence on the entire back. Sometimes no additional steps are needed after an LBL or a belt lipectomy has been performed.

For precise preoperative planning of any body-contouring operation, we suggest using the anatomic description by Strauch and colleagues (seen on p. 2856).

Treatment of the Upper Two Folds

We rarely see an isolated upper breast fold; therefore our method of choice is the ULTL, which we usually combine with a breast lift and an upper arm lift. The ULTL is also our method of choice when two folds are present, such as an upper breast fold and a lower scapular fold. If the old folds are more distinct or the fat excess is greater, we generally start with liposuction in a single operation.

For a patient with Pittsburgh grade 3 folds that are heavy and reach the spine, direct excision either in an oblique direction (referring to the relaxed tension lines) or in a horizontal direction may be indicated. Horizontal excisions, crossing these relaxed tension lines, usually result in unfavorable scars, although hiding them under the bra straps is easier than for vertical incisions.

Treatment of the Lower Two Folds

Good results can be obtained with an LBL and a belt lipectomy for treating the lower two folds. Even without direct treatment of the annoying lower thoracic rolls in patients with moderate folds, the folds can be reduced by the mechanism of *draw and counterdraw* (stretching one side to reduce the other side). Additional mobilization with liposuction is often necessary in patients with distinct hip rolls; this results in a supplementary lifting effect of this region.

OPERATIVE APPROACH: UPPER TWO FOLDS

Liposuction Alone

We do not usually use liposuction-only for contouring the back folds but for treating back rolls of massive-weight-loss patients, because of the poor shrinkage capabilities of the thick skin of the back and because of the subjacent fibrous tissue, as seen in these two patients.

Markings

Back rolls should be carefully marked before the operation with the patient both standing and then lying down, because once the patient is positioned prone on the operation table, the rolls essentially disappear, thus making it nearly impossible to determine the areas of soft tissue excess.

Technique

We always use tumescent infiltration and superwet technique. Infiltration of the entire back is essential to achieve a consistent result. Then we massage the area to distribute the fluid among the fatty tissue. For liposuction we use 3 to 4 mm cannulas and a low suction pressure (0.3 bar). We start at the top and use a crisscross technique to avoid dimples and to achieve better skin retraction. The surgeon should not suction in the rolls alone but should cross their folds. Careful pinching provides essential information about the thickness of the tissue. Liposuction is stopped at the hip rolls, where we perform some superficial refinements with a 2 mm cannula. The procedure is complete when the tissue thickness is consistent all over. The patient wears a compression garment for 2 to 4 weeks.

Indirect Excisional Procedures

If there is an indication (after the LBL) for indirectly treating the two upper folds (the upper breast and lower scapular folds), we use an approach from the lateral thoracic region with a local excision for indirect lateral and dorsal thoracic rejuvenation.

Upper Lateral Thoracic Lift

Assessment and Markings

81-1 Upper lateral
thoracic lift

Our preferred method for moderate upper folds with more than 2 to 3 cm of overlapping skin is the ULTL (for Pittsburgh 3). To better assess whether this technique is appropriate for meeting the patient's expectations, it is helpful to grab the tissue in the lower axillary region and give it a good pull to see how much of the upper back folds will disappear or remain. In most cases, this lateral pull test will provide the surgeon and patient with a clear idea of what can be achieved.

The ULTL is usually carried out in combination with a breast lift and upper arm lift. Typically a moderate extension of the incision that sweeps toward the back becomes necessary if an additional scapular fold exists. This means it is possible to achieve transposition and rotation of the soft tissue upward and outward so that the scar will be located in a medial or posterior axillary line.

For such an indirect excisional procedure without concomitant liposuction of the back, we position the patient supine with the upper arms at a 90-degree angle. This affords good access to the posterior resection line; however, in special cases we may place the patient in a lateral position, which results in considerable additional operating time.

With the ULTL, the breast fold is directly excised, and the laterocaudal tissue is removed through the lower incision. Balancing of the scapular fold can be achieved at the same time.

The ULTL can be carried out as a single maneuver just to address the back rolls, or, as is done in many of our cases, it can be used after an upper arm lift and breast lift to connect the lateral scar from the mastopexy procedure with the axillary end of the arm lift scar.

After carefully pinching and watching how much lateralization of the breast occurs with the patient supine, we begin the incision at the curved ventral line. Because there is no clear definition of Scarpa's fascia at this level, we do not go too deep and leave a small amount of fat on top of the deep fascia. This helps to protect underlying nerves, such as the lateral thoracic nerve and lower intercostobrachial branches.

Once the incision has been made and preparation has been completed to the dorsal resection line, we carefully pull the ventral wound edges dorsally, estimating whether the breast shows a tendency to move laterally. If there is too much lateralization, we suture the deep layer of the ventral wound edges down to the deep muscle fascia to provide a good anchor, usually with 2-0 Monocryl.

Then we pull the dorsal flap over the ventral wound edge and complete the resection. Before closing the wound with the dorsal tissue surplus, we pleat the tissue and tailor-tack it with towel clamps or staples.

Combination Technique

In the vast majority of cases we treat our patients using a combination of liposuction and a lateral thoracic lift (CLTL). With this combination we can reduce the considerable tendency of the tissues to develop a seroma from direct undermining, and with liposuction we obtain additional movement of the otherwise poorly mobile fascial strands. However, because of the simultaneous liposuction and the greater degree of mobilization of the tissues, the upper incision line should be placed higher than for a standard body lift incision. The same applies to the mobilization of the two upper folds toward the axilla. Later shrinking effects appear to have no clinical relevance to the location or position of the scars.

Upper Folds

If a combination technique is planned, we place the patient prone initially so that we can treat the entire back first. This yields two benefits: the adipose tissue is reduced to an acceptable thickness, and we gain some additional release of the adherent tissue. That leads to more mobility upward and laterally toward the axilla. Then we turn the patient onto the back for the lifting procedure, as described previously.

Lower Folds

Although hip folds are sufficiently resectable with an LBL, the lower thoracic folds are more difficult to address. The upper incision line can be raised to catch at least half of the fold; however, the scar will be visible above the patient's underwear.

Attempts to address the lower thoracic fold by direct undermining through an LBL will lead to a massive seroma collection and severe wound-healing problems as a result of cutting the lower perforator vessels of the latissimus dorsi. We recommend not undermining the area above the LBL incision.

To eliminate the lower thoracic fold, we usually place the LBL incision higher than usual and perform a thorough liposuction above. This deflates the lower thoracic and hip rolls and enables us to move the tissues downward so that the scar will lie within the area covered by underwear. During liposuction we address the rolls in a crisscross manner to disrupt the connective bands and adhesions to the deep fascia.

Upper Lateral Thoracic Lift in Combination With Upper Arm and Breast Lift

In most of our cases we combine the ULTL with an upper arm lift and a breast lift to treat the whole unit. We start with the arm, usually with a double ellipse technique, as described by Aly. At the axillary end of the incision, we open up for the ULTL as described and close it completely. We then address the breast with the patient in an upright position, usually with the Rubin technique, to preserve volume and prevent bottoming out.

This sequence ensures that the areola is not placed too laterally and that we are able to compensate for the lateral pull being created with the ULTL.

We usually break the scar with a Z-plasty at the level of the axilla to prevent the scar from contracting primarily. If necessary, this can be staged to be performed later.

DIRECT EXCISIONAL PROCEDURES

Bra Lift

If the lateral pull test does not correct the entire deformity on the back, a direct excision with a horizontal or curved elliptical incision should be considered. While the surgeon is pinching and adjusting the amount to be resected, he or she pays attention to the thickness of the flap between the fingertips. We recommend proceeding as described by Aly, employing the double ellipse technique for the arms and thighs and using liposuction to thin out the flap that will be resected; otherwise, it may not be possible to close the wound, because the dermis of the back is thick and rigid.

With the patient's arms elevated, the bra markings are made, and the folds are marked (note the unequal number of folds bilaterally). The tissue excess is estimated and pinched.

The markings for the upper incision line and lower estimation line are shown. If the deformity is located more laterally, we extend the lower incision line like a W-curve.

The patient is placed in a prone position with the arms abducted 90 degrees. Infiltration and liposuction of the marked areas are performed. Thorough, careful liposuction in all layers preserves the lymphatic vessels in the deep layers. An incision is made from the top and continued downward, leaving a little fat on top of the deep fascia. The lateral extent of the Scarpa's fascia roll usually correlates with a separate deep fat structure that needs to be resected. It is advisable to reconstruct the fascia afterward to avoid dimpling.

We continue with the incision downward to the estimated lower resection line and do not go below this to prevent any dead space. We then do a final check of the lower resection line and proceed with careful resection and closure. Usually we insert two drains and apply compression garments, which the patient wears for 2 to 4 weeks.

The scar may be positioned within the bra line or within the relaxed tension lines of the back.

Upper Body Lift

To treat the whole upper body circumferentially as one unit, we use the upper body lift, which includes the following:

1. Breast lift
2. Arm lift
3. Upper lateral thoracic lift
4. Back lift (upper breast and lower scapular folds via bra lift)

The procedure is indicated primarily for massive-weight-loss patients with severe circumferential deflation. The procedure employs a combination of the four lifting procedures described previously.

Full Lateral Thoracic Lift

A full lateral thoracic lift (FLTL) with vertical excisions in the midaxillary line may be indicated in very select cases after a circumferential procedure in which there is still a skin and soft tissue surplus in the hips and/or upper abdomen as well as up-

per back folds. Careful pinching will demonstrate the potential result on the front and back with a vertical incision. In some cases it is advisable to break the scar line with a Z-plasty.

Postoperative Care

As for any other patient after a significant loss of weight, a standard antithrombotic treatment regimen with antithrombotic stockings and chemoprophylaxis is initiated. Prophylactic antibiotic therapy has not been necessary in our experience, and we avoid it to prevent the development of antibiotic resistance. We initiate patient ambulation on the day of surgery. We prefer that the patient be placed in a supine position in bed, even if a direct incision was done on the back; moving the patient is much easier when the patient is supine.

The patient wears a special compression corset for 4 weeks after liposuction of the back, with or without any lifting operation. After treatment of the lower folds only by an LBL, we do not order a special compression corset for the first 1 or 2 weeks, because we have concluded that compression of this circumferentially resected area may result in further reduction in perfusion (possibly causing delayed wound healing).

For at least 3 months silicone sheets are applied to the operated areas to improve maturation of the scars.

Problems and Complications

As in other body-contouring procedures, seromas frequently form in the back and hips. Even after radical liposuction, sporadic aspiration may be required, since cavities may develop in the septated fatty tissue and will fill with serous fluid.

Because of the risk of seroma, if a direct excision is performed, we suggest leaving a certain amount of fat beneath the underlying fascia to reduce flap shearing on the fascia. We further recommend the use of an ultrasonic scalpel to avoid heat while cutting and to seal the lymph channels. Wound drains are essential, as well as the compression garment previously mentioned. Wound dehiscence usually occurs in combination with seroma. Seromas are a minor complication if adequate preparation and closure have been done and there is no dead space. The axilla has a slightly higher risk of complications, such as wound-healing problems, because mobility in that region is high, and hygiene is poorer.

Subcutaneous depressions may result from liposuction that is overaggressive and too superficial. These are very hard to correct. They may be avoided by using a correct liposuction technique with a fine cannula and limited suction pressure.

Minor wound dehiscences and wound-healing problems are not uncommon after LBL procedures. Shearing forces especially put tension on the scars and should be avoided. The key to good scar formation is a well-defined preparation and suturing technique, careful tissue handling, and suture material that is patient compatible.

Outcomes

Upper body–contouring procedures have gained wide popularity among massive-weight-loss patients and are today performed as part of multistage body reconstruction after weight loss, whether the reduction has been from a nutritional regimen or a bariatric procedure. Technical improvements enable plastic surgeons to sufficiently treat the upper truncal contour to achieve patients' goals and expectations.

Depending on the patient's preoperative BMI, indications for direct excisional procedures of the dorsal thoracic region are rarely seen in patients with mild to moderate weight loss, and occasionally are appropriate in patients after massive weight loss. Although satisfactory results can be achieved with this approach, unfavorable scar placement and scar quality restrict the implementation of this procedure.

A more common and favorable procedure for improving the contour of the dorsal thoracic region is the ULTL. With this procedure the surgeon can eliminate appropriate amounts of tissue in various anatomic units. Optimal scar placement is possible, and the procedure can be performed alone or as an integral part of a combined contouring procedure of the upper arm, the lateral and dorsal thoracic wall, and the female or male breast. In women it is usually combined with an inverted-T pattern breast reshaping, elongating the submammary incision to the axillary crease. In men after massive weight loss we perform the direct excisional procedure for breast reshaping, optionally with a free nipple graft, as popularized by Aly, or as a pedicle transfer, as described by Rubin and colleagues. The submammary scar is ideally placed at the inferior boundary of the pectoralis major muscle and is well hidden at the lateral thoracic wall to the axillary crease.

Scar formation in upper body contouring is well accepted by patients, although results differ widely in quality and appearance as a result of the atonic skin quality with poor elasticity after significant damage to extracellular matrix components that can occur from bariatric surgery. In this regard, patients should be told that revisional surgery might be necessary, because the rate for secondary corrections in this patient group is relatively high as a result of skin and tissue relaxation.

Results

This 24-year-old man had reached a BMI of 62 at a weight of 210 kg (462 pounds). He then lost 130 kg (286 pounds) through diet and vigorous sports activities. He maintained a stable weight for 2 years and presented with a preoperative circumferential vertical excess of skin and soft tissue at the lower and upper truncal regions. His main complaint was the local fat depots in the hip region, which were extremely resistant to reduction despite his weight-loss efforts. In addition to excision of the gluteal skin excess, he asked that the lower scapular folds be eliminated bilaterally and requested breast and arm lifts. The patient is shown 3 months after a circumferential lower truncal dermatolipectomy, followed by an FLTL combined with breast reconstruction using a free nipple-areolar graft, and arm lifts. His vertical tissue excess and lower scapular folds were reduced sufficiently.

This 39-year-old woman had her greatest BMI of 64 at a weight of 176 kg (388 pounds); she lost 91 kg (200 pounds) after a gastric bypass procedure, and her weight stabilized at 86 kg (190 pounds). When initially seen, she had a circumferential vertical and horizontal excess of skin and soft tissue at the lower and upper truncal regions. Although a preoperative BMI of 31 and the documentary appearance might seem to indicate the need for further weight reduction, the patient felt absolutely comfortable with her weight, which she considered to be her ideal body weight.

The patient is shown 9 months after a circumferential lower truncal dermatolipectomy, 6 months after breast reconstruction in the technique described by Rubin, and 3 months after a direct horizontal excision in the dorsal thoracic region. The horizontal excision eliminated the preexisting lower scapular folds, including an incomplete upper breast fold on the right thoracic wall. Postoperative scar formation was impaired by scar dehiscence on the left dorsal thorax. Fortunately, the scar line was well hidden in the bra line.

This 43-year-old woman had lost 45 kg (100 pounds) 19 years earlier and had undergone breast reshaping and an abdominoplasty 17 years earlier. She had her greatest BMI at a weight of 183 kg (404 pounds), lost 113 kg (250 pounds) following a gastric bypass procedure; her weight stabilized at 68 kg (150 pounds). She presented with an extraordinary circumferential vertical and horizontal excess of skin and soft tissue at the lower and upper truncal regions, with multiple skin folds in the abdominal regions as well as dominant lower scapular folds, and less defined upper breast and hip folds. After reconstruction of the lower trunk by circumferential lower truncal dermatolipectomy and an inner thighplasty, the upper trunk was reconstructed initially with an upper arm lift and in the final step with a ULTL, in combination with breast reshaping with round silicone implants placed subpectorally.

She is shown 3 months after the final stage demonstrating an outstanding overall contour; she was very pleased with the results. The less than optimal scar quality in the axilla may require minor scar revision, which would be scheduled at the earliest 12 months postoperatively.

This 24-year-old man lost 82 kg (180 pounds) through diet and exercise. His BMI was 31 before a first-stage circumferential lower truncal dermatolipectomy; further weight loss was resistant to any soft tissue reduction in the area of the lower trunk. He was able to stabilize his weight at 78 kg (172 pounds). The first-stage procedure produced remarkable improvement of the lower trunk; significant recontouring in the gluteal region resulted in high patient satisfaction. The entire upper trunk was improved through a total upper body lift, including contouring procedures in the upper arm, lateral thoracic wall, and breast. The breast was reconstructed with a free nipple graft, setting the scar into the inframammary fold to emphasize the male breast shape, as described by Aly; the scar continues into the axillary region.

The patient is shown 6 months after the circumferential lower truncal dermatolipectomy and 3 months after the upper body lift. The upper trunk is greatly improved, as are the breasts, arms, and lateral and dorsal thoracic wall. The upper breast and lower scapular folds were eliminated by means of an indirect excisional combined lateral thoracic lift. Reconstruction of the inner thigh region is planned as a final step.

Clinical Caveats

The entire posterior, lateral, and anterior trunk should be considered as independent aesthetic units. Recognizing this, planning for treatment of the upper trunk should include an analysis of every single unit to achieve optimal results in a minimum of stages.

Lower body-contouring procedures such as circumferential lower truncal dermatoilipectomies should be performed initially, followed by upper body procedures.

Upper body procedures can be performed in single steps or as combined techniques to reduce operative and recovery time and produce superior results.

The correct choice of technique is the key to producing patient satisfaction. Generally speaking, massive-weight-loss patients are much more tolerant of longer scars than they are of a procedure that results in insufficient skin and soft tissue reduction.

Liposuction in massive-weight-loss surgery is commonly performed as an adjunct technique for contour refinements or may be performed preceding various excisional procedures.

Upper lateral thoracic lifts enable elimination of redundant skin and soft tissue in the lateral and dorsal thoracic regions by placing a well-hidden scar in the lateral thoracic region. This procedure can be performed alone or as an integral part of an upper body lift.

To prevent scar contractions in combined techniques, a Z-plasty can be included at the axillary crease level.

Horizontal back excisions that cross the relaxed tension lines usually result in unfavorable scars, although hiding horizontal scars under the bra straps is easier than with vertical incisions.

The postoperative recovery after upper body-contouring procedures can be compared with that for lower body-contouring procedures, although initially after upper trunk procedures, a patient's mobility in activities of daily living is impaired to a greater degree.

Key elements in optimizing the outcome of surgery is careful patient selection, optimal choice of procedure, careful preparation and dissection, gentle tissue handling, awareness of physiological changes, and the optimal choice of closure technique.

Continued

Clinical Caveats—cont'd

The closure technique, especially the choice of suture material, can greatly affect scar outcome. Any patient incompatibility to suture material should be determined beforehand, since it can result in delayed wound healing and impaired scar quality and appearance. Nevertheless, secondary scar or wound revisions should be undertaken as appropriate.

Complications can be reduced by cautious procedure planning and precise markings, which will reduce operative time and lead to minimal tissue handling and damage.

Complications that occur frequently in lower body-contouring procedures, such as seromas and minor wound separations, are less often associated with upper body-contouring procedures.

In general, patients with a lower BMI before surgery have fewer complications and a superior result.

Annotated Bibliography

CHAPTER 82

Body Lift: *Belt Lipectomy*

AL S. ALY, ALBERT E. CRAM

Techniques for altering body contour have evolved significantly over the past century. Initially only dermatolipectomy techniques were used, but in the 1980s, when liposuction was introduced, it facilitated the ability of plastic surgeons to refine body contour with minimal scarring. Early on there was enthusiasm that liposuction might replace dermatolipectomy procedures completely. Although liposuction is still, and probably will always be, the most commonly performed body-contouring technique, it has limitations, especially in the area of skin retraction. In patients who have skin that will not conform to underlying structures after liposuction, dermatolipectomy is still required to effect the desired body contour.

Early in the twentieth century, truncal contouring was limited to excision of the pendulous pannus. Subsequently, abdominoplasty, in its various forms, was introduced for the treatment of abdominal wall laxity and skin excess. Currently, abdominoplasty is best used in patients with truncal deformity limited to the anterior abdomen. For patients who have a more generalized deformity of the trunk, abdominoplasty is inadequate. In fact, incomplete or partial treatment of patients with circumferential excess may lead to worsening of lateral and posterior contours. Thus, to treat the trunk as a unit, circumferential management is required. If the circumferential excess is mild to moderate, combining abdominoplasty with liposuction may achieve the desired contour. However, as the lateral and posterior excesses increase, there is a greater and greater need to extend the excisional component of the procedure around the trunk, eventually leading to the need for circumferential resection.

There are many names in the literature for circumferential dermatolipectomy/torso-plasty: *circumferential* or *extended panniculectomy*, *central body lift*, and *lower body lift*. We prefer the term *belt lipectomy*, because conceptually all of these procedures involve a combination of “lifting up” and “pulling down” of different aspects of the truncal anatomy. The word *lift* is somewhat inaccurate in this context. In this chapter, body lifting will be discussed in a wide variety of patient populations and will be referred to as belt lipectomy.

Evolution of Technique

The first surgeon to coin the term belt lipectomy was González-Ulloa in 1961. He used the technique on massive-weight-loss patients and described multiple turns in the operating room. Baroudi subsequently described many body-contouring excisional procedures, including circumferential truncal resections. Dardour and Vilain briefly described their belt lipectomy technique on patients with massive weight losses; it placed the final scar at midabdomen and may have added rectus fascia plication. Hunstad treated his obese patients by circumferential dermatolipectomy, extensive truncal liposuction, and subscarpal direct fat excision of the abdominal flap.

A number of other investigators subsequently contributed to our understanding of circumferential truncal contouring. Perhaps the most significant contribution to modern body contouring was made by Lockwood when he introduced the use of the superficial fascial system as an anchoring layer during closure of massive excisional procedures. This type of closure has led to better scars and a greater ability to excise more abnormal tissues during dermatolipectomy without the fear of dehiscence. He introduced a number of lower body-lift procedures that have paved the way for others in the pursuit of excellence in body-lifting surgery. Most recently, we critically evaluated a large series of belt lipectomy patients in a review article in which we delineated guidelines for patient selection, introduced a classification scheme for patients undergoing belt lipectomy, defined the truncal deformities encountered in our patient population, evaluated the effects of surgery on different groups of patients, and quantitatively reported on our complications.

Principles of Belt Lipectomy

Belt lipectomy is a combination of the following components:

- Abdominoplasty
- Lateral thigh lift
- Buttocks lift
- Liposuction of various areas

However, a belt lipectomy is not simply combining these procedures. The complexity of combining these procedures, and the wide variety of body types that can benefit from body lifting, make belt lipectomy a difficult procedure to master, with a significant learning curve. Although the procedure has some basic features that are common to most patients, the details of the technique are adjusted to each patient's present needs. For example, the technique used in a massive-weight-loss patient who is still obese is different in detail from the technique used on a patient in the normal weight range.

Belt lipectomy is an extensive procedure. It requires multiple turns of the patient in the operating room, results in a very large area of surgical injury, and leaves a long circumferential scar. Although it is possible for a single experienced surgeon to perform a belt lipectomy alone, it is often necessary to use an experienced assistant to reduce potentially long operative times.

Complications are not uncommon with this type of surgery, and both the surgeon and the patient must be willing and able to deal with setbacks. The postoperative recovery can be long, in some cases up to 6 weeks, which can cause strain for the patient and surgeon alike. Patients require both physical and psychological support for a relatively long recovery period.

The trunk is a body unit, with the thorax constituting the superior subunit, and tissues from the lower aspect of the thorax to the pelvic rim constituting the inferior subunit. The *unit principle* described by Millard dictates that when one is reconstructing defects, it is best to reconstruct the whole unit and place the final scars along natural junctions or between anatomic units. Burget and Menick, in discussing reconstruction of the nose, emphasized the importance of creating proper contour matching of the natural topographic nasal anatomy within each reconstructed subunit. Belt lipectomy surgery is an extrapolation of these important principles, applied to the trunk. The surgeon's goal is to create proper contour of the inferior subunit of the trunk and to place the resultant scar in natural junctions.

Another major advantage of circumferential dermatolipectomy procedures, despite their being extensive and associated with significant morbidity, is the high patient satisfaction rate. Studies conducted on patients who have undergone belt lipectomy demonstrate an improvement in the overall truncal contour in a wide variety of patients, as rated by both the surgeon and the patient.

Indications and Contraindications

Indications

There are many patients who can benefit from a belt lipectomy. Their presentations, goals, and outcomes vary considerably. They are grouped here into clinically relevant categories.

Massive-Weight-Loss Patients

Advances in bariatric surgery and the recognition of obesity as a leading health risk factor in the United States, have led to an increase in the number of patients requesting body contouring after massive weight loss. Although the medical benefits of weight loss, such as reduction or elimination of diabetes and high blood pressure, are by themselves worth the time and effort, the resultant body contour in most patients is less than ideal. Often these patients are surprised and dismayed by their appearance. If they are able to undergo body-contouring surgery, it can be the final step in their life transformation. Post-massive-weight-loss body contouring is the new frontier in plastic surgery, and it will become one of its major subspecialties in the near future.

The plastic surgeon will see a wide range of body contours and sizes in massive-weight-loss patients. These individuals also have differences in the thickness of subcutaneous fat, skin-fat envelope redundancy, and in their fat deposition patterns.

Multiple factors have been found to contribute to the diversity encountered with massive-weight-loss patients. The first and most important is their BMI at presentation. BMI relates the patient's weight to their height and is the most commonly used obesity index. It is calculated as shown in the box on p. 2890.

Calculating Body Mass Index

$$\frac{\text{Weight in kilograms}}{(\text{Height in meters})^2}$$

or

$$\frac{\text{Weight in pounds}}{(\text{Height in inches})^2} \times 703$$

The upper limit of normal is 25; 26 to 29 is considered overweight; 30 to 35 is considered obese; and greater than 35 is considered morbidly obese.

The actual weight-loss process, whether from bariatric surgery or changes in lifestyle, will stabilize or plateau at different levels in different individuals. The level of this plateau is not easily altered. Thus BMIs at presentation will range on a continuum from individuals who are still significantly obese to those who are near their ideal weight. A second factor contributing to the diversity in presentation is the quality of the skin fat envelope, which includes its thickness, elasticity, and, what is most important, what we have coined as the *translation of pull*.

The translation of pull is determined by pinching tissues in the proposed area of resection, simulating the effects of the surgical resection on the tissues above and below. This patient demonstrates a significant translation of pull, which can be seen by the patient and surgeon before surgery. The third major factor affecting the diversity of massive-weight-loss patients is their genetically controlled fat deposition pattern, which dictates the amount and location of fat during weight gain and loss.

Although quite variable in presentation, massive-weight-loss patients share a common factor: almost all will have an inverted-cone appearance to their inferior trunk—narrower at the ribcage and wider at the pelvic rim. Anteriorly, they have varying degrees of pendulous panniculi and may have one, two, or, occasionally, three rolls. It is not clear why these extra rolls develop, but there are probably fibrous connections between the skin and underlying muscle fascia that are similar to the inframammary crease anatomically. Almost all massive-weight-loss patients will present with some degree of abdominal wall laxity. Many also have hernias of varying sizes and locations, especially patients who have had open bariatric surgery procedures. The mons pubis frequently has ptosis, lipodystrophy, and varying degrees of vertical and horizontal excess. The opening of the vulva in women and the takeoff of the penis in men will face downward to varying degrees, rather than the normal anterior vector.

Laterally, massive-weight-loss patients will lack definition of the waist because of excess tissue hanging from the narrower ribcage to the relatively wider pelvis, which tends to camouflage the underlying anatomy. Many patients have fairly large and distinct hip rolls. The lower back is often indistinct from the superior aspect of the buttocks. Some patients have lower back rolls; others do not. The buttocks in many patients are overprojected and simply blend superiorly with the hip excess, giving the buttocks a vertically long appearance. In other patients, the buttocks may have no excess in posterior projection but often still lack definition. The superior extent of the central buttocks crease in some is fairly low, and it may be combined with a loss of soft tissue cover over the coccyx. The infrabuttock crease varies greatly in presentation, depending on the BMI. When patients are still in the obese range, the infrabuttocks creases are usually very abnormal in appearance and are horizontal rather than semicircular. In patients who have reached BMIs near their ideal body weight, often the infrabuttocks creases will show redundancy.

The goals for an individual patient may vary within the massive-weight-loss group, but in general, there is a desire to return the patient's truncal contour to the normal range for the general population. More specifically, goals in the abdominal area include elimination of hanging tissue and restoring a flat contour. If the mons pubis is ptotic, it should be lifted to a more superior position to produce an anterior-facing vulva in women and an anterior penile takeoff point in men. An hourglass figure, with narrowing at the waist, should be reconstituted, although to a lesser degree in a male patient. Posteriorly, lower back rolls should be reduced or eliminated. A clear delineation between the lower back and buttocks should be created. The desired improvement in the buttocks proper is highly dependent on the initial presentation. If the buttocks are overprojected, they should be reduced. If they are already underprojected, they should be better defined but not reduced in projection. The central buttocks crease in some patients requires elevation to a more superior position. If possible, the infrabuttocks crease should be altered to approximate a normal semicircular appearance.

A subgroup of massive-weight-loss patients includes individuals who have undergone anterior truncal resections but are still unhappy with persistent lateral dog-ears, a lack of definition in the waist, and lack of improvement in posterior truncal contour. The number of patients presenting in this manner is increasing as massive-weight-loss patients are either convinced to, or choose to, undergo resections limited to the anterior trunk. The goals of this subgroup of patients are similar to those of massive-weight-loss patients who have not undergone these resections. Depending on the extent of their initial procedure, these patients may need a full belt lipectomy, a modified belt lipectomy, or a partial belt lipectomy limited to the lateral and posterior resections.

Non-Massive-Weight-Loss Patients

Patients Who Are 20 to 30 Pounds Overweight

Non-massive-weight-loss patients usually request either liposuction or an abdominoplasty but are 9 to 14 kg (20 to 30 pounds) over their ideal body weight. They have usually tried to lose the weight over many years but have been unable to, despite genuine attempts. They may be young with good skin elasticity, or older with significant skin laxity. Typical truncal contour deformities include abdominal wall laxity, skin and fat excess, and lateral and back excess. Many will have lower back rolls and buttocks ptosis. They may or may not have lateral and medial thigh lipodystrophy. If these patients undergo simple abdominoplasty, significant lateral dog-ears may be created, and their lateral and posterior contours will not be improved. If liposuction is combined with abdominoplasty, adequate improvement may be achieved. However, this combination of procedures will not result in lifting of the lateral thighs

and buttocks or a more defined waist, especially if the typical abdominoplasty incisions are not extended around to the back. The goals for this group of patients include a flat abdominal contour, waist and hip definition, elimination or reduction of lower back rolls, raising and definition of the buttocks, and reduction in lateral thigh excess and ptosis. These patients start out with bodies that are within the norm for the overall population, and they desire a greater shift toward ideal when compared with many massive-weight-loss patients.

Normal-Body-Weight Patients

Patients of normal body weight present with abdominal wall laxity and/or skin excess. They also usually have different degrees of isolated fat deposits in the lateral thighs and hip regions. Most patients who present in this manner can benefit from abdominoplasty, with liposuction of the areas involved with lipodystrophy. The reasons for considering belt lipectomy in this group include a desire for significant anterior and lateral thigh elevation, buttocks elevation, and a remarkable improvement in lower truncal contour.

Contraindications

As with any elective surgery, belt lipectomy should not be performed in patients with significant medical or psychiatric problems. The possible fluid shifts and alterations of intravascular volume during a belt lipectomy can stress a less than optimally functioning heart. Almost all patients who undergo a belt lipectomy will need a significant amount of abdominal wall tightening by various forms of rectus fascia plication. As the abdominal wall is tightened, the intraabdominal contents are pushed up onto the diaphragm and in turn onto the lungs, leading to some restriction of pulmonary capacity. In patients who have significant lung disease, pulmonary compromise may occur. Thus patients with significant chronic obstructive pulmonary disease (COPD) or restrictive lung disease are not good candidates for belt lipectomy. With the inherent compromise of blood supply of undermined abdominal tissues during the procedure, conditions associated with decreased vascularity, such as smoking, are to be avoided in most instances. We have recently performed belt lipectomy on well-selected diabetic patients; however, it is not clear at this point whether this will become routine.

Patients who have lymphedema of their anterior abdominal pannus are not good candidates for belt lipectomy, since they will almost universally redevelop lymphedema and a hanging pannus. It is best to avoid such extensive surgery in the face of almost certain failure, and such patients should be counseled accordingly.

Patients with excessive intraabdominal content are not good candidates for belt lipectomy. The illustrations below demonstrate why this is true.

Conceptually, the inferior trunk can be thought of as two balloons, one inside of the other. The outer balloon is the skin and the inner balloon is the abdominal wall musculature, within which the intraabdominal contents are contained. Fat is contained between the two balloons and inside the abdominal cavity.

If both balloons are overinflated by weight gain and subsequently deflated by weight loss (*second from left*), then reducing the outer balloon without being able to flatten the inner balloon will lead to a persistently convex contour (*third from left*). The appearance of a patient with excessive intraabdominal content after a belt lipectomy is similar to a patient who undergoes a simple panniculectomy. Since a panniculectomy is a simpler and less risky procedure, obese patients who have excessive intraabdominal content are advised to lose weight or undergo a traditional panniculectomy. Thus a basic requirement for patients undergoing belt lipectomy is that their intraabdominal contents allow abdominal wall flattening by rectus fascia plication.

Hormonal manipulation of body fat content is an emerging field in the medical management of obesity. In general, growth hormone deficiency is associated with an increase in both subcutaneous and intraabdominal fat, with a preferential increase in intraabdominal fat. Growth hormone replacement will lead to an overall decrease in body fat content, with a relatively greater loss of intraabdominal fat. Testosterone is also known to decrease the overall body fat content, with selective activity at the intraabdominal level. Thus in the future it may be possible to use these hormones to decrease intraabdominal fat in patients who tend to retain it after massive weight loss to allow better abdominal wall tightening during body-contouring procedures.

Pertinent Anatomy

The soft tissues over the inguinal region and at the junction between the hip and lateral thigh fat deposits are anchored by zones of adherence consisting of fascial attachments that restrict both elevation and descent of the tissues surrounding this region. The inguinal region zones of adherence, along with a variable-strength suprapubic zone of adherence, create a lower abdominal area of restriction that is responsible for why a hanging pannus hangs. It is also these horizontal zones of adherence that are essential to understanding how to control scar position in the marking process. There is a weak midline abdominal zone of adherence that is usually inconsequential to excisional body-contouring procedures.

The blood supply of the abdominal flap after its elevation off the underlying muscular fascia is reduced to the lateral intercostal, subcostal, and lumbar vessels, as shown. Although this is similarly encountered in a traditional abdominoplasty, the blood supply in a belt lipectomy maybe jeopardized to a greater extent when some techniques are used in particular patients because of the need for more extensive lateral dissection of the abdominal flap.

Massive-weight-loss patients also have various zones of adherence in the superior truncal subunit of the thorax.

Preoperative Assessment

History and Physical Examination

A complete history is taken and a thorough physical examination is conducted on all patients being considered for belt lipectomy. The patient's weight history, exercise routine, and nutritional habits are documented. Patients whose weight is fluctuating when they are initially seen should not be operated on until they reach a stable weight. Patients who are in the midst of heroic efforts to lose weight, such as starvation diets or overly taxing exercise regimens, should not be considered candidates, because most patients are not able to sustain such efforts over a lifetime. Patients with significant medical problems, uncontrolled psychiatric difficulties, and smokers are not good candidates and should be counseled accordingly.

As stated, postoperative recovery from a belt lipectomy is long, and complications are not uncommon. Even for patients with adequate psychological reserves to handle such stress, psychiatric difficulties can arise. Many massive-weight-loss patients present with a concurrent psychiatric illness and are at risk for acute flare-ups during recovery. A preoperative psychiatric clearance should be considered in these patients.

The patient's BMI should be determined. Although the BMI is not always accurate, especially in an athletic male with a relatively large muscle mass, it is helpful for predicting results and potential complications. The patient's overall body contour is examined circumferentially, with close attention to the inferior truncal subunit, thighs, thorax (superior truncal subunit) and upper arms.

The surgeon must determine the extent of abdominal wall laxity and whether the amount of intraabdominal content is excessive. In patients within the normal weight range, this is determined by abdominal wall palpation and the classic "diver's test," in which the patient bends forward from the waist, revealing any abdominal wall laxity. This is more difficult to determine in patients with higher BMIs but can be established by placing the patient in the supine position and observing the abdominal wall contour. If the abdomen is scaphoid, it is likely that the intraabdominal contents are not excessive, which should allow rectus fascia plication to tighten and flatten the abdominal wall. Conversely, if the abdomen in the supine position is convex and protrudes above the ribcage, intraabdominal content is excessive and belt lipectomy should not be considered as an option. The surgeon should search thoroughly for hernias, because it is not unusual for patients to have incisional, ventral, or periumbilical hernias. The patient's fat distribution pattern and skin quality should be examined. Subcutaneous fat thickness and skin mobility over the underlying muscular anatomy are noted. Generally, thinner subcutaneous fat layers increase the likelihood that the skin will be fairly mobile when resection is attempted. For patients who have had bariatric surgery, the following laboratory tests should be obtained: complete blood cell count, blood urea nitrogen, creatinine, electrolytes, glucose, urinalysis, liver function, iron, calcium, albumin, prealbumin, total protein, and thiamine. Chest radiographs and electrocardiograms are obtained if indicated.

Patient Education

Because of the magnitude of belt lipectomy surgery, patients should be counseled extensively in the preoperative period. This will help the patient and the surgical team develop rapport, which is invaluable in the relatively long postoperative recovery period. Both the patient and plastic surgeon should clearly understand the presenting deformities and the patient's realistic goals. An overview of the surgery, the typical postoperative course, and the possible risks and complications should be thoroughly discussed. This is especially important because patient cooperation is essential in preventing complications in the early postoperative period. For many patients, especially massive-weight-loss patients, body-contouring surgery is the culmination of a life transformation, and it may be the toughest hurdle from a physical, psychological, and financial standpoint for them. Thus it should be presented to them as a "major life event."

Preoperative Planning

Markings

The markings are usually done 1 or 2 days before surgery. These are photographed; the surgeon evaluates the photos and may make changes based on the findings. As with the whole field of body lifting, the markings have evolved and will continue to evolve to produce the best results and to adjust to new and unique problems. The markings are different for every patient, and the sequence described here is intended to be a starting point from which to diverge and adjust to attain the best result.

A number of concepts should be stressed in performing the markings:

The money is in the belly. The abdominal contour attained after surgery should be as good as possible given a particular patient's anatomy. It should be of higher priority than the posterior contour in treating most patients because it is the area of greatest deformity, especially in the massive-weight-loss patient, and it is also the most visible area to the patient.

The lateral resection should be maximized. The patient's lateral contour is also very important and should be stressed because it is highly visible and easily judged by the patient. Although in some patients the waist region does not need significant improvement, in most patients it is essential that this area be contoured as aesthetically as possible.

The markings delineate the superior and inferior extents of a circular excision in an inverted-cone shape. If the circumference of the superior proposed line of excision (A) is compared with the circumference of the inferior proposed line of excision (B), A is always shorter. Occasionally the distances are equal,

but *B* is almost never shorter than *A*. This is important, because it explains the fact that in almost all patients there is no need to decrease upper truncal horizontal excess, as would be attempted with a fleur-de-lis pattern.

The markings should be considered as guides to the resection. The actual resections should be adjusted to intraoperative tension.

The patient's anterior midline is marked. In non-massive-weight-loss patients, the horizontal mons pubis mark is made similar to the marking for traditional abdominoplasty, usually at the natural suprapubic crease. A massive-weight-loss patient is placed in the supine position, the mons pubis is pulled up into a pleasing appearance, and the pubic bone is palpated. At a point 1 to 2 cm above the bone, the horizontal mark is made from one lateral edge of the mons to the other. In some patients this may lead to eliminating as much as 15 cm of hair-bearing skin.

With the patient in the supine position and slightly bent at the waist, a line is drawn from the lateral aspect of the mons pubis and directed toward the anterior superior iliac spine (ASIS). The mark is made after the abdominal tissues are manually elevated superomedially to estimate the amount that the inguinal tissues will lift. The zone of adherence in the inguinal region limits the extent of this lift. This maneuver simulates tissue dynamics at closure and allows the surgeon to predict final scar position to a great degree. The pull of the manual elevation of the flap simulates the superomedial pull of the resected abdominal flap. The inguinal zone of adherence acts to limit that elevation. We prefer a "French bikini" angulation of this mark, with the line drawn aiming slightly above the ASIS. If the surgeon prefers a flatter-angled scar, the same superomedial elevation of the abdominal tissues is performed, and the scar is drawn where the surgeon wants it.

The proposed superior extent of the anterior resection is marked. Centrally, the mark is made similar to that for a traditional abdominoplasty and should not be tempered by the subsequent back resection, because the anterior resection is stressed over the back resection. In non-massive-weight-loss patients it is usually just above the umbilicus, whereas in massive-weight-loss patients the mark may be considerably higher. Because of the circumferential nature of belt lipectomy, the lateral abdominal excisions are marked without concern for possible dog-ears, as in the case of abdominoplasty markings. The markings are made with the aid of the pinch technique and should be as aggressive as they need to be to create a flat lateral contour. Laterally, the superior proposed mark should be made fairly flat, because angulating this aspect of the mark may lead to compromise of some of the remaining abdominal flap intercostal, subcostal, and lumbar vessels. In turn, this can cause central flap necrosis.

Anteriorly, the inferior marks control scar position.

With the patient standing, the back midline is marked. A decision has to be made as to the vertical level of the posterior resection. In many patients this is a fairly easy decision, because the area of posterior excess is fairly well delineated by the natural anatomy. In others it is not evident, and the surgeon has to decide on the level based on the desired goal. Some patients have excessive buttock protrusion, and their resection level should include the superior aspect of the buttocks proper to allow for an appropriate reduction. Other patients have normal or less-than-normal buttock projection, and the level of resection in these patients should be more superior to avoid decreasing the projection farther. Part of this decision is also based on the surgeon's aesthetic sense and the patient's desires. Once the level of resection is decided on, the inferior midline mark is made.

The superior extent of the midline back excision is marked with the patient flexed at the waist to approximate the bent position in which the patient will be at the completion of the anterior resection. *This is a very important step in preventing wound dehiscence.*

The inferior aspect of the back excision is then marked from the midline toward the lateral aspect of the trunk. Centrally, a shallow widow's peak is created at the midline, and bilateral lazy S's are drawn. In most patients the areas that need the greatest elevation posterolaterally are the lateral buttocks and lateral thigh regions. Resecting more laterally in these regions will create a better lateral contour and will improve the shape of the infrabuttocks crease in most patients.

The superior extent of the back excision is marked using the pinch technique. Generally, this mark is placed fairly close to where the actual final scar will end up, since back tissues are restricted in their movement because of their stronger zones of adherence, whereas buttocks tissues are quite mobile. Thus tissues from the buttocks and lateral thighs are lifted to the position of the superior incision in this region rather than the lower back tissues descending to the inferior tissues.

Posteriorly, the superior marks control final scar position.

At this point in the marking process, both the anterior and the posterior marks are in place. There may be a transition from the anterior to the posterior marks. Superiorly, connecting the anterior and posterior marks is usually not difficult, because they typically line up well. Inferiorly, in some patients the anterior mark may be significantly higher than the posterior mark. A compromise then needs to be made between these marks. The anterior marks are lowered and the posterior marks are raised. Often this transition will fit in the natural creases, especially in massive-weight-loss patients. The patient is then placed through the operative positions, supine and both lateral decubitus positions, and the marks are checked for symmetry and whether they are reasonably placed.

A series of vertical marks is made to facilitate alignment at closure, because many patients who undergo a belt lipectomy have tissues that become significantly distorted in the operative positions. In patients with an extremely ptotic and redundant mons pubis, normal contour should not be expected nor promised. A compromise should be accepted rather than risking overresection, which can potentially lead to permanent lymphedema of the mons pubis. After complete healing from belt lipectomy, a separate mons puboplasty can be considered and discussed with the patient.

With typical markings, the vertical marks are helpful in aligning tissue during closure. Often two sets of lines are drawn as possible superior extents of resection, and the appropriate line is used at surgery based on the tension encountered.

Markings continue underneath the hanging pannus. If the patient needs lateral and anterior thigh liposuction, those areas are marked.

Operative Technique

Because of the circumferential nature of belt lipectomy, it is not possible to perform the total resection using a single body position in the operating room. Both the number of body positions employed and the sequence in which they are used can be varied and will differ from surgeon to surgeon. Based on the need to stress the anterior resection over the posterior resection and to maximize the lateral resection, the sequence of supine-lateral/decubitus-lateral/decubitus has been found to optimize the results and will be described here.

Preoperatively the patient has an epidural catheter placed for postoperative pain management. We have found that epidural analgesia considerably reduces the risk of deep venous thrombosis/pulmonary embolism; thus chemoprophylaxis is not used. If the surgeon chooses not to use an epidural—which most will not—they should consider the use of chemoprophylaxis, although it is not easy to determine the best regimen to use.

Sequential compression stockings are put on the patient in the holding room. The patient is then taken to the operating room and placed in the supine position on the operating table with an underlying beanbag. Symmetry is checked before induction of general anesthesia. Once general anesthesia is induced, the arms are placed at a 90-degree angle and padded, and an indwelling urinary bladder catheter is placed. An 18-gauge needle dipped in methylene blue is used to tattoo the vertical marks above and below the extents of possible resection. The methylene blue tattoos will last for a few weeks and are very helpful for tissue orientation at closure.

Because the anterior resection has to end where the patient's body makes contact with the operating table, a temporary dog-ear is marked in the shape of a V. This area is temporarily closed with staples at the end of the anterior resection. The patient is then prepared and draped.

Two 2-0 silk sutures are placed through the skin of the superior and inferior umbilicus as traction sutures. If the umbilical stalk needs to be shortened, the sutures can be placed deeper within the umbilicus. A circumbilical incision is then made and dissected down to the level of the rectus fascia with some fat left on the stalk.

The anterior abdominal inferior mark is then incised and carried down to the level of the Scarpa's fascia. The abdominal flap is elevated superiorly, at or just below Scarpa's fascia up to the umbilicus. In patients with a thin pannus, the dissection is carried up to the costal margins and xyphoid, indicated above by the methylene blue chevron-shaped marks. In patients with a thick pannus, the supraumbilical dissection is limited to the medial edges of the rectus muscle fascia and the flap is liposuctioned directly to thin it.

Patients with scars from an open cholecystectomy are at risk of tissue necrosis inferior to the scar if that tissue is elevated off the underlying muscle fascia and advanced as the inferior aspect of the abdominal flap. In these patients, the proposed superior mark is incised first. A limited central supraumbilical dissection is performed, just

enough to allow advancement of the flap to the proposed inferior marks. The blood supply of the tissue inferior to the cholecystectomy scar is then examined. If it appears viable, the inferior flap is elevated down to the level of the inferior marks and is then tailored to the superior mark. If the tissues appear to be vascularly compromised, all of the tissue below the cholecystectomy scar is resected and the inferior flap is elevated and tailored to the level of the resection at the cholecystectomy scar. In this case the final scar is going to be much higher onto the abdomen, and the mons pubis will most likely not be addressed adequately, requiring a secondary excisional procedure.

Abdominal wall plication is performed with a nonpermanent, running, long-lasting, barbed suture. If any hernias are encountered, they are treated before the plication is done. In a small number of patients the umbilical stalk is part of the hernia sac and may need to be sacrificed.

The infraumbilical plication is usually performed before the supraumbilical plication, because this is the area of greatest laxity in most patients, especially women.

During plication, peak respiratory pressures should be checked. Most patients' respiratory pressures will rise mildly with the plications, but if they are significantly elevated, restriction of pulmonary function could develop. This can be avoided by making certain that the patient does not have excessive intraabdominal contents during the preoperative examination.

The patient is then flexed at the waist and the abdominal flap is redraped inferiorly and tailored to the inferior incision. As the flap is redraped, it is also conveniently split in the inferior midline. Splitting the flap facilitates the initial flap elevation in a patient with a large hanging pannus.

Ferguson clamps are used during tailoring of the abdominal flap. Extensive amounts of anterior abdominal excess will often need to be resected in massive-weight-loss patients. Laterally, in the area of the previously marked V, the temporary dog-ear is stapled.

In patients who have midline vertical supraumbilical scars, occasionally the scar is tethered and may prevent advancement of the inferior flap during the tailoring procedure. In these patients the surgeon makes a series of horizontal nicks in the vertical scar to release the scar and allow appropriate advancement. We prefer not to resect the scar during a belt lipectomy, because it increases the risk of vascular compromise of the distal aspect of the abdominal flap at the T intersection.

A closed suction drain is placed and brought out through a lateral stab incision. If the patient requires liposuction of the anterior and medial thighs, this is performed either through the open abdominal wound or through appropriate stab incisions. The proper location of the umbilicus is then determined with the abdominal flap temporarily tacked in place with Ferguson clamps. A vertical 1.5 to 2 cm incision is made in the midline at the chosen location. The fat deep to the incision is bluntly dissected apart to allow a path for the umbilicus.

Three nonpermanent sutures (we prefer 3-0 Monocryl) are placed at the 3, 6, and 9 o'clock positions at a subcuticular level on both the abdominal flap and the umbilicus, as well as through the surrounding rectus fascia to help invaginate the umbilicus when the sutures are tied. The remainder of the umbilicus is sutured to the abdominal flap with simple interrupted, nonpermanent, subcuticular sutures.

Before abdominal closure, a series of interrupted quilting sutures are placed from the abdominal flap to the rectus fascia, to help close dead space. We think that this reduces the risk of seroma formation.

The abdominal wound is then closed in multiple layers, the first and most important layer being the reapproximation of superficial fascia, or Scarpa's fascia. One of the authors (A.S.A.) prefers to use Quill 1 PDO nonpermanent, long-lasting, running barbed suture to reapproximate Scarpa's fascia, whereas the other author (A.E.C.) prefers 0 PDS nonpermanent, long-lasting, interrupted sutures. We have found no difference in scarring between these different closures. The next layer of closure is accomplished with nonpermanent subcuticular staples. The final layer is closed with a running subcuticular 2-0 Monocryl temporary suture. Finally, tissue glue is applied to the skin to complete the closure.

The patient is then turned over to one of the lateral decubitus positions, which allows maximal resection of the lateral trunk and more direct access to the lateral thighs for liposuction. To accomplish the turn efficiently and safely, five or six people should be involved. One person is assigned the responsibility of making certain the patient is flexed at the waist to prevent dehiscence. Multiple pillows are placed between the knees to flex the hip as much as possible. All pressure points are padded, an axillary roll is placed, and the beanbag is molded and hardened to hold the patient in the desired position. In this position, resection from the created lateral dog-ear to the midline of the back is performed. If lateral thigh liposuction is needed, it is also performed while the patient is in this position.

The lateral and back marks are reinforced and the vertical marks are tattooed in this position.

Just past the midline of the back, a temporary V-shaped dog-ear is again marked to allow for the subsequent turn.

The patient is prepared and draped again in this position. The lateral thigh is suctioned if necessary. Unlike the anterior resection, the superior mark is incised first during the back resection. The reason for this is twofold. First, most patients have more inferior than superior laxity in the lateral trunk, so it is best to dissect inferiorly rather than superiorly to lift the ptotic buttocks and lateral thighs. Second, the back has tendency to develop seromas, and less dissection in this area is desirable. The level at which the inferior flap is elevated is based on the patient's anatomy. If the patient has overprojected buttocks, as is the case in most high-BMI patients, the dissection is performed at a level just above the muscle fascia, leaving a small amount of fat on the fascia.

If the patient has underprojected buttocks, the elevation is performed at the level of the superficial fascia so that as much fat tissue as possible is left behind. In either case, the flap is elevated at least to the level of the proposed inferior line of excision. The dissection can be carried down as low as needed to get the desired amount of tissue resected; not infrequently, this can be down to the level of the midbuttocks.

This illustration demonstrates the extent of direct elevation (*blue*) and possible indirect, or discontinuous, lateral thigh elevation (*green*), usually performed with a large, unconnected liposuction cannula.

The inferior flap is then redraped superiorly and, with the aid of Ferguson clamps, tailored accordingly. The vertical marks, placed every 10 cm or so, are extremely helpful in aligning tissue at this juncture.

In patients with excessive buttocks protrusion, there is a discrepancy in thickness between the lower back and the buttocks. Tailoring of the inferiorly based flap should be more aggressive in the fat deep to the superficial fascia to equalize the thickness of the subcutaneous fat of the two edges brought together. This is an important step in helping create a smooth transition between the buttocks and the back, which many of these patients lack. If there are still small discrepancies after closure, liposuction can be performed to create a smooth contour from the waist through the hip and down onto the lateral thighs and buttocks.

One closed suction drain is placed in the back through a stab incision made laterally. The closure of the back is similar to the anterior closure. Just past the midline, the temporary dog-ear is closed with staples to allow for the final turn.

The patient is turned to the other lateral decubitus position, and the other side of the resection is completed in a similar manner. Occasionally, the second side does not allow for as much resection of tissue as the first side; thus the surgeon should not assume that the same amount can be removed.

After the second side is completed, the patient is placed in the supine position on the operating table, with the waist flexed to the appropriate position. This turn, as all other turns, requires five or six people to accomplish safely, with one person making certain that the waist is flexed appropriately. There is the danger of causing abdominal flap necrosis with circumferential compression; thus compression garments are not routinely used.

After extubation, the patient is placed on a flexed hospital bed under the guidance of the surgeon to prevent dehiscence.

Adjunctive Procedures and New Concepts

Upper Body Lift

Belt lipectomy addresses problems of the inferior subunit of the trunk, from the ribcage to the pelvic rim. For non-massive-weight-loss patients, the procedure addresses their problems well, since their deformities are usually limited to the inferior subunit. Massive-weight-loss patients, on the other hand, often have problems involving the superior subunit of the trunk, or the thorax.

When thoracic soft tissues are inflated by obesity and then deflated by weight loss, they will hang lower than their original position, onto the underlying skeleton, with the exception of the zones of adherence located at the anterior and posterior midlines. The soft tissues overlying the midlines thus are tethered, while the rest of the thoracic tissues are free to hang down as a curtain drapes down from two tethering pleats.

The region of greatest descent is located at the midaxillary line, because that is the greatest distance from the zones of adherence. Anteriorly the breast will demonstrate varying degrees of ptosis. The nipple-areola complexes will often appear medially displaced, but this is an optical illusion, because the lateral inframammary crease is free to descend, while the midline zone of adherence tethers the medial inframammary crease. The transition from the lateral breast onto the lateral chest wall usually is in the form of a roll that is an extension of the lateral breast and may extend onto the back as an upper back roll. In some patients a second roll is also present. The upper back roll occurs in various sizes and will travel in a superior direction toward the midline posterior zone of adherence. Overall, the thorax has both vertical and horizontal excess as a result of the deflation of weight loss.

In massive-weight-loss patients, the upper arm excess often spills onto the lateral chest wall. This is important, because most brachioplasty techniques do not address the lateral chest wall excess, which is part of the horizontal thoracic excess created by massive weight loss.

The constellation of upper truncal deformities in massive-weight-loss patients has not received much attention, because the abdominal pannus tends to be the overwhelming problem that massive-weight-loss patients complain about—and what insurance companies are willing to pay for. However, as these patients become more familiar to plastic surgery as a whole, there will be greater emphasis on all their areas of deformity, including the thoracic region.

The individual massive-weight-loss patient may or may not have any or all of the thoracic deformities described here. The deformities depend on the amount of weight gained and lost and on the patient's genetically controlled fat deposition pattern. Each of these deformities can be treated separately, or together in a single procedure.

Massive-weight-loss patients have upper arm excess that is in continuity with the thoracic tissue's horizontal excess is marked preoperatively for a brachioplasty technique that crosses the axilla, onto the lateral thoracic wall. Previously we would perform a Z-plasty in the axilla to avoid the potential for scar contracture, but we have abandoned its use as part of the primary procedure, using it only in a secondary procedure if a contracture occurs.

An advantage for patients who undergo brachioplasty with this technique is the excellent contour achieved, as can be seen in these two patients. This level of improvement is usually not attainable in massive-weight-loss patients if techniques limited to the axilla are employed.

The lateral thoracic rolls, or lateral breast rolls, that extend onto the back to differing degrees as upper back rolls, are usually not eliminated by belt lipectomy. Thus if the patient desires elimination of these rolls, a direct dermatolipectomy will be required (see Chapter 83). This resection eliminates the rolls and lifts the lateral thoracic tissues into their proper anatomic position, which includes lifting the lateral inframammary crease to its correct location and creating its normal upward sweep. It also shortens the vertical excess created by the weight loss. Subsequently, lifting or reducing breast tissue can be performed based on a correctly positioned inframammary crease.

This massive-weight-loss patient underwent a *complete upper body lift* that combined brachioplasty, lateral breast/upper back roll excision, and breast surgery. Pre-operatively the patient had upper arm excess that crossed the axilla and involved the lateral thoracic wall, prominent lateral breast rolls, and descent of the lateral inframammary crease.

The upper body lift shortened both the horizontal and vertical excess of the thorax and allowed the augmentation-mastopexy to be performed based on the corrected position of the lateral inframammary crease.

Another important anatomic area that is especially difficult to treat in massive-weight-loss patients is the thigh region. The thighs in some patients have minimal or no abnormality, even after fairly large amounts of weight gained and lost. These patients simply never deposit fat in their lower extremity because of their genetically programmed fat deposition pattern and do not require treatment. In others, large amounts of fat are deposited in their lower extremities and lost along with the rest of their body fat as they reduce their weight. Depending on the amount of excess re-

maintaining, either a medial thigh lift or a medial thigh lift combined with a vertical-component dermatolipectomy is necessary. Another less fortunate group will gain weight in the lower extremities with their weight gain, but they are genetically programmed to retain that fat, even after significant losses in the remainder of the body. This group requires a combination of a reduction of fat content in the entire thigh region and a subsequent dermatolipectomy. To accomplish this safely, the thighs require fairly aggressive circumferential liposuction to create a deflation similar to the one created by the massive weight loss in the truncal region. To tighten and lift the thighs, 3 to 6 months after liposuction, direct excision of both horizontal and vertical excess is necessary.

Postoperative Care

Immediately after belt lipectomy surgery, wound dehiscence is of greatest concern because of the circumferential nature of the closure. A carefully followed regimen of prevention is instituted beginning in the operating room. At the end of surgery the patient is transferred to a flexed hospital bed by the operating surgeons. The patient's body position is maintained in the flexed position during the transfer. Unlike an abdominoplasty, in a belt lipectomy the patient cannot be overflexed to relieve tension on the anterior wound, because that may lead to undue tension on the posterior wound. Conversely, the patient cannot be flattened at the waist, because this would lead to undue tension on the abdominal closure. A large sign is placed on the hospital bed indicating to the nursing staff that the patient is not to be moved, even in minor ways, until he or she is completely awake and alert. Postoperatively, the patient is the only person who can actually sense tension on the different aspects of the wound, so he or she is extensively instructed on this point preoperatively. When the patient is awake and alert on the day of surgery, ambulation is initiated with assistance, and the patient is expected to guide others regarding positioning during ambulation to prevent dehiscence.

If the patient has an epidural catheter, the anesthesia team adjusts its infusion to relieve pain but not affect motor function so that the patient is able to ambulate. The epidural infusion is continued through the morning of the second postoperative day. The urinary bladder catheter is left in place for at least 4 hours after the epidural infusion is discontinued. The patient's diet is advanced to a regular diet soon after surgery. Once pain control is stabilized on oral medications, the patient is ready for discharge, with instructions about drain management. The average hospital stay for a belt lipectomy patient is 2 to 3 days. If the patient does not have a good support team at home, the surgeon should insist on a longer stay.

The patient is instructed to maintain the flexed position for 1 week. At the end of the week the patient is instructed to practice slow straightening exercises. Most patients will be able to stand up fairly straight by 10 to 14 days after surgery. Drain management for any surgical procedure is widely variable and depends on the surgeon's philosophy and experience. Belt lipectomy is no exception, but drain management is particularly important because of the relatively high incidence of seromas, especially in massive-weight-loss patients who have high BMIs. We do not think that any particular protocol of drain management will actually decrease the rate of seroma formation, but a reasonable approach is to start removing drains that reach the criterion of less than 40 ml of drainage per 24 hours, starting the third day after surgery. In most cases the anterior drains will reach this criterion within the first 7 to 10 days. The posterior drains will usually be the slowest to reach this criterion, and in some patients they will not have reached it at 14 days. In this instance, a sclerosing agent is injected through the drain every 2 to 3 days in an attempt to decrease the size of the pocket. We prefer to use doxycycline as the sclerosing agent. Once the drainage drops to approximately 80 ml per day, the drain is removed and the possible seroma is dealt with through serial aspirations. Early in the postoperative period the use of compression garments should be individualized to the patient, because circumferential compression in this group of patients can potentially cause skin necrosis of the lower abdominal flap. We use compression garments after concerns about flap vascularity have passed, usually 4 to 5 days after surgery. Patients are instructed to keep the garment on as much as they can tolerate for up to 6 months.

Patients can usually return to normal, nonvigorous activity after 4 to 6 weeks. They are advised to slowly increase their activity level, depending on how they feel, with really strenuous exercise discouraged for at least 3 months. Swelling superior to the scar, especially anteriorly, will be significant and apparent for at least 3 months. Overall truncal contour will start to stabilize in appearance at about 1 year but can continue to improve for years, especially if the patient loses more weight.

Complications

We evaluated 70 consecutive belt lipectomy patients; 85% were women and 15% were men. Fifty-six percent had at least one complication, 21% had more than one complication, 44% had no complications at all, and no deaths occurred in the series. Complications occurred in 55% of women and 56% of men. When complications were stratified according to BMI, it was noted that the rate of complications increased as the BMI increased. Seromas were the most frequent complication, occurring in 30% of patients, with an increase in frequency as the BMI rose. The fairly large number of seromas can be attributed to the very large area of dissection, with most of these fluid collections occurring in the back (back dissections are associated with seromas in general). Small wound separations occurred in 20% of the patients,

with a few fascial dehiscences requiring surgical intervention. Dehiscences were caused by mechanical stress on the wounds, which mostly occurred within the first 24 hours after surgery.

Preventing patients from moving until they are completely awake and instructing them to guide their own ambulation are very helpful in reducing this problem. The other cause of dehiscence is large seromas that cause breakdown at the wound edge to allow drainage. Detection and frequent aspiration of seromas will help reduce that risk. Infections occurred in 4.3% of the patients and were almost always associated with seromas. They were controlled through appropriate seroma drainage and antibiotic therapy. Pulmonary emboli occurred in 2.9% of the patients. To prevent this serious complication, all patients were required to wear sequential compression garments intraoperatively and while in their hospital bed. They were also ambulated as soon as possible after surgery.

Despite such efforts, these problems can still occur, and any suggestive symptoms should be investigated. Since this study was conducted, we have used postoperative epidural analgesia, and the rate of DVT/PE has dropped to zero.

Lower midline abdominal flap skin or fat necrosis occurred in 4.3% of the patients. In two patients, the lateral abdominal flap was tailored at an acute angle to match an acute angulation of the inferior line of resection that traversed from the lateral mons pubis to the ASIS. This was done to create a high French bikini line-shaped scar. This is believed to have led to a reduction of the number of lateral perforators reaching the inferior midline of the abdominal flap. Thus it is wise to avoid extreme angulation of the lateral abdominal flap. Another cause of abdominal flap necrosis was encountered in two patients who had a midline supraumbilical scar that had to be resected to allow advancement of the abdominal flap at closure. When the abdominal flap is incised in the midline, there is a reduction of the blood supply at the level of the subdermal plexus to the inferior medial edge of the skin on each side. If this is combined with aggressive resection of the abdominal flap in the vertical direction, leading to significant tension at closure, vascular compromise may occur. Thus, as previously mentioned, we have abandoned the practice of resecting tethered midline scars and replaced that with serial stab incisions to release the flap.

Outcomes

In properly selected patients who undergo belt lipectomy, significant improvements in their inferior truncal contour can be achieved. The outcomes of surgery can be categorized into two main groups: massive-weight-loss patients and non-massive-weight-loss patients. Each group can be further divided into subgroups that can help the surgeon better predict the possible outcome for a particular patient. The classi-

fication of patients discussed here, which is based on weight at presentation, is helpful in predicting outcome. However, it is not the only telling factor, because the patient's fat distribution pattern and the absolute decrease in BMI from the greatest to the lowest weight are also important.

Massive-Weight-Loss Patients

This group of patients is defined as any patient whose weight at one time was in the obese range (a BMI of 30 or above) and subsequently lost a significant amount of weight. Although generally that amount is often felt to be at least 45 kg (100 pounds), patients who are small in stature can lose less weight and still qualify as massive-weight-loss patients. The results that can be expected from this group of patients are divided into clinically relevant subgroups according to the weight at which they stabilized before surgery. As a general trend, the lower a patient's BMI at presentation, the closer to normal his or her body contour will be after surgery.

Still Significantly Obese With a BMI of 35 or More

The subgroup of patients who still have a BMI above 35 will achieve significant improvement in their inferior truncal contour through belt lipectomy, but generally they do not attain what is considered normal for the overall population. They often have other body areas, especially the thighs, where a significant amount of fat is still retained, preventing an appearance of normality. They have a very significant increased risk of complications, seromas being the most common problem. Often they will require treatment of other areas of the body to reach the norm for the population.

Near Ideal Body Weight With a BMI of 28 or Less

The closer a patient is to ideal weight at presentation, the better the final contour after belt lipectomy. Commonly the subcutaneous fat layer encountered in this subgroup of patients allows the overlying skin to move freely over the underlying muscular framework. This permits the surgeon to resect larger amounts of excess skin and to transmit the effects of the pull on tissues located far from the areas of the resection. This subgroup of patients generally achieves a remarkable improvement that will place them in the normal range of body contour; some even attain ideal body contour. Their complication rate is relatively low, especially when compared with the still-obese subgroup of patients previously discussed.

Intermediate Weight Level With a BMI of 29 to 34

Patients in this intermediate subgroup generally attain results that are intermediate between the two subgroups discussed previously and would be considered on a continuum between them. They will attain a significant improvement in their inferior truncal contour and would generally be considered to have body contours within

the norm for the overall population. Their results are similar to the group that is 20 to 30 pounds overweight discussed below. Their complication rate is intermediate between the two subgroups mentioned previously.

Massive-Weight-Loss Patients Who Have Undergone Anterior Resection

This subgroup is composed of massive-weight-loss patients who have had dermato-lipectomy procedures limited to the anterior abdomen. They are grouped separately because they have distinct complaints; this group is growing in increasing in numbers. Typical patients in this group are initially seen with the complaint that before their previous surgery they were told that they needed only an abdominoplasty or panniculectomy. After that surgery was performed, these patients are often disappointed with the increased lateral prominence caused by the limited anterior resection's dog-ears and the lack of improvement of the waist, hips, back, and buttocks. Depending on the patient's contour at presentation, a partial, modified, or full belt lipectomy will be appropriate. The results can be predicted based on the BMI categories described previously.

Non–Massive-Weight-Loss Patients

Patients 20 to 30 Pounds Overweight With a BMI of 26 to 29

This subgroup comprises patients who are 9 to 14 kg (20 to 30 pounds) overweight, have not been able to lose the weight despite real attempts, and have never been appreciably heavier. A significant improvement in their inferior truncal contour is generally attained with surgery. They start out with contours that are within the norm for the general population and will attain significant improvement toward an attractive contour with belt lipectomy. Results in this subgroup are similar to those of the intermediate subgroup in the massive-weight-loss group discussed earlier. Their complication rate is also similar.

Normal-Body-Weight Patients

Patients who are at or near their ideal body weight may have abdominal wall laxity and/or skin excess amenable to abdominoplasty; they also usually have different degrees of isolated fat deposits amenable to liposuction. However, they will specifically desire remarkable elevation and definition of their buttocks contour, and some patients will request more waist definition. The postoperative abdominal and lateral truncal contour in this subgroup of patients usually demonstrates the typical effects attained by abdominoplasty, in addition to remarkable improvement in buttocks contour that would not be attainable by liposuction alone. These patients present within the norm of the general population and should have a remarkable improvement in their inferior truncal contour after belt lipectomy.

Results

The following patient examples demonstrate the results attainable in the patient categories that have been discussed. These cases show variations of technique and deformities and help to delineate the limitations of belt lipectomy.

This 33-year-old woman reached her highest weight at a BMI of 45. She lost 45 kg (100 pounds) after bariatric surgery and presented with stabilized weight at a BMI of 29. She is shown before and after undergoing a belt lipectomy. Her postoperative photographs demonstrate an excellent improvement in her inferior truncal contour with elimination of the pannus, flattening of the belly, elevation of her mons pubis, creation of waist definition, and elevation and definition of the buttocks. Although her lower back rolls were eliminated, the upper truncal deformities were minimally affected and more outlined after belt lipectomy. The same can be observed in her thigh region. Thus both the superior truncal subunit and the thighs will need further surgical intervention.

This 52-year-old woman's BMI at her greatest weight was 49. She subsequently underwent a gastric bypass procedure and lost 36 kg (80 pounds) before stabilizing at a BMI of 37. She is shown before and after undergoing a belt lipectomy. She presented with a preoperative circumferential inferior truncal excess of skin and fat, mons pubis ptosis, abdominal wall laxity, and a fairly unique pattern of hip lipodystrophy. The pattern of posterior resection used in this patient was adjusted inferiorly to address the prominent hip roll. After a belt lipectomy, her abdomen is flat, the mons pubis is partially elevated, and the extra hip roll is eliminated. Because her presenting BMI was still in the morbidly obese range, her improvements, although significant and very much appreciated by the patient, are tempered by the fact that she still has an overall body contour that would not be considered within the norm for the whole population. Her fat deposition pattern dictates that her lower extremity has persistent lipodystrophy after significant weight loss, which contributes to the less than ideal body contour. Patients in her weight range often have a thick subcutaneous fat layer that reduces the mobility of the skin-fat envelope over the underlying muscle fascia. This prevents improvement of anatomic contour located at a distance from the actual dermatolipectomy resection, such as the infrabuttocks creases.

This 31-year-old woman who had triplets and then another child reached her highest weight at a BMI of 41. She subsequently lost 26 kg (60 pounds) as a result of lifestyle changes, reaching a BMI of 30. She is shown before and 14 months after surgery. She presented with significant abdominal wall laxity, a single roll pannus, mons pubis ptosis, and a lack of waist definition. Her buttocks appeared long vertically and lacked definition but were not overprojected. The surgical technique we employed had a more superiorly positioned posterior excision, because she did not need a reduction of her posterior buttocks projection. Placement of the scar in the posterior vertical position chosen allowed the surgeon to create the desired depression in contour at the junction of the back with the buttocks. This was accomplished by thinning the inferior advanced flap. If the scar had been placed lower, onto the buttocks proper, this maneuver would not have been possible, because it would have created a depression in the superior buttocks area.

Postoperatively, the patient has a flattened abdominal contour and an elevated mons pubis, and an attractive waistline has been created. Her buttocks are better defined and appear shorter in the vertical dimension. Note that this patient does not need surgery to the upper truncal subunit or the lower extremity, which correlates with her range of BMI.

This 38-year-old woman had reached a BMI of 42 before losing 45 kg (100 pounds) through diet and exercise. At presentation, her BMI was 25 for a total drop of 17 in BMI. She is shown before and 1 year after surgery. Postoperative photographs reveal elimination of her hanging skin, flattening of the abdomen, elevation of the mons pubis, increased soft tissue cover over the coccyx, increased buttocks definition, and improvement in the redundancy below the infrabuttocks creases. Because she had a relatively significant drop in her BMI, she presented with a small amount of subcutaneous fat. This allowed the surgeon to “translate the pull” to greater distances from the line of resection, especially compared with patients who have a much thicker subcutaneous fat layer. Thus the significant improvement of the infrabuttocks creases and the moderate improvement of the anterior thighs can be attributed to her thin subcutaneous fat layer. Patients in this range of BMI will often attain a near-ideal body contour after surgery.

This 44-year-old woman originally reached a BMI of 72. She lost more than 91 kg (200 pounds) after gastric bypass surgery and stabilized at a BMI of 33. She is shown before and after undergoing a subsequent belt lipectomy. The procedure was adapted to her open cholecystectomy scar, which required a reverse approach to the abdominal resection. Thus her abdominal superior incision was made first during the anterior resection, at the level of the cholecystectomy scar, and the inferior flap was adjusted to the superior flap. This resulted in a more superiorly positioned anterior abdominal scar.

Excellent contour was achieved through the surgery, but she continued to lose weight, reaching a BMI of 25 at the time the postoperative photographs were taken 1 year after surgery. However, she did not feel well at that weight and intentionally gained weight to reach a BMI of 26.6. It is unusual for a stabilized weight-loss patient to lose the remarkable amount of weight this patient did. Her BMI of 33 at presentation would ordinarily predict less improvement than she actually has attained. The better-than-expected improvement is the result of the very large drop in BMI, which led to greater elasticity and redundancy of the skin-fat envelope and thus provided the surgeon a greater ability to resect the excess.

Overall, she has a remarkable improvement in her circumferential inferior truncal contour. Her pannus was eliminated and a flat abdominal contour achieved, her mons pubis was elevated, her waist was defined, and her lower back rolls were eliminated. Her buttocks contour at a BMI of 25 was too deflated and improved with her weight gain to a BMI of 26.6, but her lateral thighs increased in prominence because of her genetically controlled fat deposition pattern. The upper truncal subunit contour was unaffected by the belt lipectomy; she will need an upper body lift to attain maximal improvement in those areas.

Preoperative

1 year postoperatively

2 years postoperatively

This 46-year-old patient is shown before and 2½ years after belt lipectomy. At presentation, she was 18 kg (40 pounds) overweight with a BMI of 31.2. She was not able to lose the weight despite multiple serious attempts over a number of years. Her complaints were concentrated on the lower truncal subunit and included abdominal wall laxity, excess abdominal skin and fat, lack of waist definition, lipodystrophy of the hips and lower back region, and ill-defined buttocks that appeared long in the vertical dimension. She was offered a traditional abdominoplasty and liposuction but was warned that her lateral excess might not be eliminated. She refused that approach and underwent a belt lipectomy. Postoperative photographs demonstrate a flat abdomen, a well-defined waist, elimination of the lower back rolls, and well-defined buttocks that appear shorter in the vertical dimension. This patient is fairly representative of patients who are 14 to 23 kg (30 to 50 pounds) overweight.

Preoperative

1 year postoperatively

4 years postoperatively

This 44-year-old woman presented with a BMI of 23. She requested improvement in abdominal contour, elimination of her right lower quadrant scarring, and reduction of her hip and lateral thigh lipodystrophy. She was offered an abdominoplasty and liposuction to the hips and lateral thighs, but elected to undergo a belt lipectomy because of her specific desire to lift and improve her buttocks contour. She is shown before surgery, 1 year after surgery, and 4 years after surgery.

After 1 year there is improved abdominal contour and an outstanding improvement in buttocks contour. Four years after surgery, she is shown after a 9 kg (20-pound) weight gain despite a continued good exercise regimen. Although she has retained benefits from the surgery, it is apparent that a rise in BMI from 23 to 27 has led to a return of some of her original fat deposition pattern.

Clinical Caveats

Patients with excessive intraabdominal content are not good candidates for belt lipectomy.

The goal of belt lipectomy surgery is to create proper contour of the inferior subunit of the trunk and to place the resultant scar in natural junctions.

There are many types of patients who can benefit from belt lipectomy, the most prevalent being massive-weight-loss patients.

Multiple factors contribute to the widely variable presentation of massive-weight-loss patients, including the BMI at presentation, the difference between the highest and lowest BMI, and the genetically controlled fat deposition pattern.

The anterior abdominal contouring aspect of belt lipectomy should be emphasized over the back resection. The lateral resection should be maximized to create the best possible lateral contour.

Belt lipectomy should be thought of as a circular excision of the lower trunk, in the shape of a “boxing championship belt,” wide anteriorly and narrow posteriorly.

Since dehiscence is of major concern in the postoperative period, the extent of the midline back excision is marked with the patient flexed at the waist to approximate the flexed position that the patient will be in after the anterior resection.

Upper arm excess in massive-weight-loss patients crosses the axilla onto the lateral chest wall and to treat that deformity, the brachioplasty technique used needs to cross the axilla.

In a massive-weight-loss patient the thorax, or the superior truncal subunit, will often have deformities that may require a combination of procedures called an *upper body lift* to normalize the appearance of that subunit.

The postoperative recovery from belt lipectomy, especially in a massive-weight-loss patient, is a long and difficult process and should not be taken lightly by the patient or the surgeon.

As a general rule, especially in massive-weight-loss patients, the lower the patient's BMI before surgery, the better the results and the lower the complication rate.

Seromas and small wound separations are the most common complications associated with belt lipectomy surgery.

Overall, complications are not uncommon with belt lipectomy surgery; the higher the patient's BMI before surgery, the higher their risk for complications.

Annotated Bibliography

Aly A, Cram AE, Chao M, et al. Belt lipectomy for circumferential truncal excess: the University of Iowa experience. *Plast Reconstr Surg* 111:398-413, 2003.

This review article critically evaluates a large series of belt lipectomy patients. The authors delineate guidelines for patient selection, introduce a classification scheme for patients undergoing belt lipectomy, define the truncal deformities encountered in their patient population, evaluate the effects of surgery on different groups of patients, and quantitatively report on their complications.

CHAPTER 83

Abdominoplasty

GILBERT P. GRADINGER,
LORNE K. ROSENFELD, FARZAD R. NAHAI

Abdominoplasty is performed to correct soft tissue abnormalities of the anterior trunk, from the lower border of the ribcage to the inguinal and pubic areas. Body contour problems involving the fat and skin of the lateral and posterior truncal regions are treated with liposuction and extended dermolipectomy.

Plastic surgeons who perform abdominoplasty have recognized that variations in abdominal contour require modifications in surgical procedure. Newer techniques require shorter incisions and eliminate umbilical circumscription. In the past, patients who sought contour reduction had only one choice—abdominoplasty. Today superior aesthetic results can be achieved in many patients with liposuction alone. Liposuction combined with abdominoplasty has enhanced our ability to achieve better results. Small fat deposits, which cannot be treated with abdominoplasty, are ideal for liposuction, which is associated with insignificant scarring, minimal inconvenience, and negligible morbidity. On the other hand, treatment of a massive-weight-loss patient mandates more aggressive and advanced techniques to repair this multifaceted deformity.

Plastic surgeons now have a much wider range of choices for operative correction of the many abdominal deformities, including the following:

- Liposuction alone
- Complete abdominoplasty with or without umbilical translocation
- Lower abdominoplasty
- High lateral tension abdominoplasty
- Fleur-de-lis abdominoplasty
- Reverse abdominoplasty

Surgery may involve one option, a variation on an option, or a combination of options.

Indications and Contraindications

The typical abdominoplasty patient is a woman (although increasingly men are also seeking treatment) who has had one or more full-term pregnancies and a subsequent loss of youthful abdominal contour. Most of these women have tried exercise and dieting but have been unable to regain their prior shape. Obesity may or may not be

a factor. Usually an excess of fat is present. The skin of the abdomen is stretched from pregnancy weight gain and subsequent weight loss. Dermal breakdown, as evidenced by stretch marks, is often present. The quality of the lower abdominal skin often determines the relative roles of surgical lipectomy versus liposuction. The status of the underlying fascia and abdominal wall muscles also dictates which surgical approach is indicated.

The patient criteria to be considered must be exhaustive if the surgeon is to avoid major complications and patient dissatisfaction. The elements of a successful abdominoplasty include the following:

Weight: Stable for more than 6 months and not grossly overweight (BMI less than 30)

Medical condition: No major medical issues such as labile hypertension, diabetes, or coronary artery disease

Psychological state: Well motivated and realistic (for example, postpregnancy or gastric bypass patients)

Habits: Regular exercise, reasonable diet, and no smoking or excess alcohol consumption

Anatomy: Absence of multiple abdominal scars and no extreme abdominal protrusion (secondary to intraabdominal fat accumulation)

Pertinent Anatomy

FARZAD R. NAHAI

When considering aesthetic procedures of the abdomen, the surgeon must be thoroughly familiar with the anatomy of the abdominal wall. A clear understanding of the blood supply and soft tissue layers is critical when planning incisions, determining the amount of tissue to be resected, and deciding whether concomitant liposuction or lipectomy is indicated. It is also important when managing the umbilicus and calculating the degree of flap elevation, especially in patients who have had prior abdominal procedures. The specific anatomy most relevant to the understanding and application of these complementary techniques includes the zones of adherence, the superficial fascial system, and the blood supply remaining after each approach.

Soft Tissue Layers of the Abdominal Wall

The abdominal wall is composed of six distinct soft tissue layers: skin, subcutaneous fat, subscarpal fat, anterior rectus sheath, muscle, and a posterior rectus fascia. It spans the area between the costal margin, midaxillary line, iliac crest, and symphysis pubis—a sort of elongated hexagon. The layers of the abdominal wall are consistent in their relationship to each other; the variability occurs with regard to the quality of the tissues and amount of fat present.

Skin

The skin of the abdomen receives its blood supply from multiple muscle and fascial perforating vessels that feed a subdermal vascular plexus. Depending on multiple patient characteristics (such as age, BMI, and number of full-term pregnancies), the skin of the abdomen can have differing degrees of elasticity. Often, the skin of the patient being considered for abdominoplasty is stretched, demonstrating poor elasticity and multiple striae. These striae are surface evidence of attenuated or absent underlying dermis. The location and extent of striae should be considered when planning skin incisions, because at the time of closure these areas of poor or absent dermis are more difficult to close and are at risk for separation. The surgeon should attempt to place skin incisions on the abdomen in such a way that the resultant scars will be covered by the patient's choice of undergarments.

Fat

The adipose layer of the abdominal wall can be divided into two layers—superficial and deep—based on Scarpa's fascia. The superficial fat layer has a more robust blood supply, is usually thicker, and has a more dense and durable type of fat. Its vascular supply is from both the subdermal plexus and the underlying musculocutaneous perforators. The deeper layer of fat is typically less dense and receives most of its blood flow from underlying muscle, making it more prone to ischemia during abdominoplasty. This difference in blood supply to the superficial and deep layers of fat is an important factor to consider during lipectomy of the abdominal flap. Because the anterior abdominal wall fat deep to Scarpa's fascia is not involved in supplying circulation to the skin, it may be excised during an abdominoplasty. Conversely, preservation of subcutaneous fat superficial to Scarpa's fascia is crucial to survival of the overlying skin.

Muscle and Fascia

There are four principal paired muscle groups of the abdominal wall: the rectus abdominis, external oblique, internal oblique, and transversalis. The common purpose of these muscle groups is to support the abdominal contents, assist in breathing, and permit the flexion/rotation of the thorax and pelvis. The external oblique, internal oblique, and transversalis muscles form the anterolateral wall of the abdomen, spanning the costal margin to the midline. The rectus abdominis originates on the anterior surface at the lower midline of the rib cage and inserts on the symphysis pubis. The aponeurotic portions of the oblique and transversalis muscles envelope the rectus abdominis and blend in the midline to form the linea alba, a dense confluence of fascia that separates the left and right rectus muscles. The arcuate line is a transition point above which the external oblique and a superficial division of the internal oblique form the anterior rectus sheath, while the deep division of the internal oblique and the transversalis composes the posterior rectus sheath. Below the arcuate line, approximately midway between the umbilicus and symphysis pubis, the transversalis aponeurosis, along with the deep division of the internal oblique muscles, progressively transfers to the anterior fascial layer, leaving only the preperitoneal fat between the rectus muscle and the underlying peritoneum.

Blood Supply

The blood supply to the muscles, skin, and fat of the abdominal wall comes from numerous major arteries of the thorax and pelvic region. These arteries exhibit many anastomotic interconnections that are important for abdominoplasty. Understanding their origins and routes is essential to avoiding ischemic complications.

For the purposes of this discussion, it is helpful to consider the blood supply to the abdominal wall from two areas: one that is superolateral in origin and the other that is inferior in origin. Superiorly, the superior epigastric artery, a branch of the internal thoracic artery, enters the posterior rectus sheath on its way into the rectus abdominis muscle as it emerges from the costal margin immediately lateral to the sternum. As it enters the rectus, it is situated medially in the muscle. It then perforates the rectus abdominis muscle, branching as it descends within the muscle until it anastomoses with the deep inferior epigastric artery. Perforators through the anterior rectus sheath, more densely present in the periumbilical area, supply the abdominal skin and fat overlying the muscle.

The other terminal branch of the internal thoracic artery is the musculophrenic artery, which passes inferolaterally deep to the ribs at the costal margin where it anastomoses with the lower and posterior intercostal vessels (direct branches of the aorta) at the last intercostal space. These posterior intercostal vessels travel between the transversalis and internal oblique muscles and have collateral, muscular, and cutaneous branches. Caudal to these are the subcostal and lumbar arteries, both dorsal branches of the thoracic aorta, which contribute to this anastomotic network of vessels that course between the transversalis and internal oblique muscles.

It is within this intermuscular space that one of the anastomoses between the superolaterally based vasculature and inferiorly based vasculature exists. The ascending branch of the deep circumflex artery, a branch of the external iliac artery, originates from the iliac crest and ascends to the aforementioned anastomotic network. The two other principal inferiorly based vessels are the paired deep inferior epigastric arteries (DIEAs), a branch of the external iliac artery, and the superficial epigastric arteries, a branch of the femoral artery. The DIEA travels superomedially from its origin, pierces the transversalis fascia, and runs along the posterior border of the rectus abdominis muscle before entering it. Once in the muscle, it branches on its way cephalad to anastomose with the branches of the superior epigastric artery. The principal perforators to the skin, on average five per side, emerge through the anterior rectus sheath more densely in the periumbilical region. These perforators receive more inflow from the DIEA than the superior epigastric artery. The superficial epigastric artery arises from the common femoral artery, 1 cm distal to the inguinal ligament at its midline, and ascends within the superficial abdominal fascia and fat toward the umbilicus. It often arises as a common trunk with the superficial circumflex iliac artery, superficial external pudendal artery, and deep circumflex iliac artery.

The Umbilicus

The umbilicus is an aesthetically important surface structure of the abdomen. It is typically situated approximately 14 cm above the symphysis pubis in the midline, or 10 cm above the pubic hair (at the level of the iliac crest). The aesthetically pleasing umbilicus is shallow, has a thin superior skin hood, and is round or elliptoid in shape. Blood flow to the umbilicus is from the subdermal plexus, in addition to three distinct sources: the principal supply is from branches of the right and left DIEAs; additional flow is from the ligamentum teres and the median umbilical ligament. Multiple branches of the DIEA ascend between the rectus muscle and the posterior rectus sheath on their way to the umbilicus. In a morbidly obese patient, the stretching and

descent of the tissues distorts the vascular anatomy and the umbilicus is elongated. Extra caution should be exercised when dissecting the umbilicus in these cases. The fascia around the umbilicus can be weak with a resultant umbilical hernia. Care should also be taken to dissect around the hernia sac to avoid bowel injury.

Nerves

Cutaneous sensation of the abdomen is derived from the lateral cutaneous and anterior cutaneous branches of intercostal nerves T7 through T12. The lateral cutaneous branches perforate the intercostal muscles at the midaxillary line to travel within the subcutaneous plane. The anterior cutaneous branches travel between the transverse and internal oblique muscles to penetrate the posterior rectus sheath lateral to the rectus muscle before entering the rectus muscle on their way to the overlying fascia and skin.

The anatomy of the lymphatic system of the abdominal wall is important, because it is clinically related to the occurrence of serous fluid accumulation and edema after abdominoplasty. A plexus of lymphatic vessels resides within the subscarpal fat layer just superficial to the anterior rectus sheath. Below the umbilicus, the lymphatic system drains inferiorly via the femoral route. Above the umbilicus, this system drains cephalad in the superficial plane to the axilla on its way to the thoracic duct.

Le Louarn and Mustoe published favorable results demonstrating that preservation of the suprafascial network of lymphatics (in addition to use of a quilting suture, in Le Louarn's case) diminishes time with a drain, and both stated that postoperative serous drain output, seromas, and abdominal flap swelling is diminished.

Preoperative Assessment

LORNE K. ROSENFELD

A comprehensive examination is crucial to enable the surgeon to properly prepare the patient and accurately plan surgery.

Physical Examination

The physical exam should include evaluation of all “layers” of the abdominal wall: the skin, the subcutaneous fat, and underlying fascia/muscle (with an indirect assessment of the extent of intraabdominal fat).

Skin

The skin examination should involve much more than just the assessment of the classic pannus of excess lower abdominal skin above the pubis.

Striae

The boundaries of striae are assessed. It should be duly noted and explained to the patient the extent of the striae that may not be included in the resection (particularly those above the umbilicus).

Excess Skin

Standing, this patient ostensibly has little excess skin

Same patient in relaxed sitting position

The extent of obvious anterior redundant skin (width of the pannus) is noted first. This evaluation determines the initial estimation of the length of the incision. However, a proper assessment must be made beyond the obvious excess lower abdominal pannus if a more complete correction is to be made at the entire anterior trunk “aesthetic unit”; that is, the extent of redundancy is evaluated not only above the inguinal area but also below the incision, at the hips, thighs, and pubis. If there is particular excess at the lateral thighs, then the incision will, necessarily be appreciably

longer, if the high lateral tension abdominoplasty (HLTA) approach is to be properly applied. On the other hand, if the patient demonstrates minimal excess laterally, then significant tension should not be planned, for fear of making the incision unnecessarily longer.

Any excess skin at the upper abdomen should be noted. Here there may be what may be called a secondary roll or wall of cascading skin, which really represents a migration of redundancy from the chest rather than the abdomen. Consequently, usually not all of this upper abdominal skin can be removed from the suprapubic approach. It is of greater value to conduct this examination with the patient not only in the supine and standing positions, but also when *sitting and bending over*. This is often the only posture in which one can see the areas of redundancy in a patient who demonstrates what appears to be primarily abdominal wall protrusion. Of equal importance, the mobility or what may be called the “translation” of the skin should be assessed, because it can be very telling; the looser the skin, the better the result.

Adhesions

The surgeon should note any adhesions of the skin at the thighs and abdomen proper. Although not previously described, adhesion can also be found at the level of the waist, particularly laterally: a waistline zone of adherence and contraction. In fact, there is most often what one may call a second roll of excess skin resting above this “valley,” most notably in the larger or weight-loss patient. This band essentially divides the abdominal excess skin into superior and inferior segments. The surgeon must be aware that this adhesion of tight skin will reliably resist the surgeon’s efforts to efface this upper abdominal excess. And because this zone harbors vital perforators, only a judicious release of the area by discontinuous undermining should be attempted. Otherwise, this upper abdominal redundancy is best addressed with either a fleur-de-lis-type abdominoplasty or a second-stage reverse abdominoplasty.

Scars

Any scars at the abdomen are assessed. Of greatest concern are those at the subcostal and midline areas. These scars require the surgeon to map out the safest and most effective surgical approach. For a subcostal scar, it is best to restrict the amount of undermining in this area and if possible even include this scar in the resection with a fleur-de-lis approach. Similarly, the upper midline scar presents a challenge. Either a fleur-de-lis-type pattern or a reverse abdominoplasty should be considered. Otherwise, the risk of abdominal flap necrosis is too high. Finally, if there is a full-length midline scar, the fleur-de-lis template is ideal.

Subcutaneous Fat

Thickness of the Envelope

A topographic sense of the extent of underlying fat must be defined. This mapping will guide where liposuction could be conducted—and just as important, where it should not be performed. Usually contouring of the waist, hips, and lateral thigh accentuates the abdominoplasty's shaping affects and assists the HLTA by facilitating the translation of pull of the skin with its liposuction-induced discontinuous dissection. If the central flap is very thick with fat, it is best to inform the patient that a second-stage liposuction surgery may be necessary to complete the repair safely.

Abdominal Wall

The Location and Extent of Protrusion

The patient is asked to relax the abdominal wall

The degree of lower abdominal wall relaxation is assessed with the patient lying down with knees bent, as well as when standing. *The patient, while standing, is asked to make a conscious effort to relax the abdominal wall.* The additional extent of protrusion that occurs is both surprising and quite informative. Besides the obvious lower abdominal wall protrusion, one should also assess the magnitude of laxity at the upper abdomen. Compressing the lower abdominal wall and watching for “herniation” of the epigastric area will accomplish this task.

The Presence of a Hernia

The exam should explore for an incisional, epigastric, or periumbilical hernia. This is particularly relevant, not only for planning to repair the defect, but also to avoid performing liposuction in these areas before abdominal flap elevation for fear of intraabdominal penetration with the cannula.

The Shape of the Waist

If the waist is square and blunted by fat, aggressive liposuction can be very beneficial.

Preoperative Photographic Documentation

It is essential to obtain a consistent and complete set of photographs. This should include one set of eight views (quarter turns) of the patient from neck to knees with the arms up and a second set with the arms down. Including the anatomic regions above and below the abdomen mandates that the surgeon assess the entire truncal “aesthetic unit” to plan the initial surgery or subsequent stages. This allows proper assessment of the potential far-reaching salutary effects of the HLTA, fleur-de-lis, or reverse approaches postoperatively.

During the photographic session, the patient is again asked to totally relax the abdomen so a true representation of wall laxity can be documented.

Additional views may be photographed, as desired:

With the patient sitting/bending over to illustrate the true excess skin that is often hiding (particularly in front of the protuberant abdomen)

With the patient grasping the excess skin to reproduce the desired lift and potential result of the surgery (for HLTA, reverse, and fleur-de-lis abdominoplasties)

Patient Education

Informed Consent

Every patient is told that the general risks of bleeding, infection, delayed healing, and undesirable scarring are common to any operation. The risks specific to abdominoplasty are also explained, including loss of skin in the lower area of the flap above the pubis, distortion or malposition of the umbilicus, asymmetry of the scar or abdominal contour, failure to narrow the waistline, and postoperative seroma. The surgeon should also clearly define for the patient the extent and limitations of the planned surgery:

The excess skin that may not be fully removed: the potential dog-ears at the lateral margins and the inevitable residual skin or even rolls at the upper abdomen, above the zones of adhesion

The potential scar at the lower midline abdomen, the original site of the umbilicus: when all lower midline skin is intentionally not excised to facilitate a tension-free closure in an aesthetic location

The possible lateral extension of the abdominal scar: depending on the amount of excess skin present, the longer the scar, often the better the result

Patient Instructions

The patient is given a set of instructions covering preoperative, intraoperative, and postoperative considerations (see p. 2948).

Patient Information

Preoperative Preparation

To ensure that the patient is optimally prepared for surgery, the following instructions are given:

The patient is assisted to accomplish a regular bowel program.

The patient is instructed to take antiseptic showers and apply antibiotic ointment to the nares for a few days preoperatively.

The patient is encouraged to continue regular diet and exercise programs.

The patient is strongly urged to stop smoking altogether, but if this is not realistic, then to discontinue all smoking for at least 2 weeks before and 2 weeks after surgery.

The patient is advised to donate 1 or 2 units of autologous blood, depending on the extent of the surgery planned.

Intraoperative Information

To promote compliance, the surgeon must inform the patient of any relevant intraoperative activities:

Antiembolism stockings and pumps will be in place before, during, and after surgery.

Binder garments, drains, a Foley catheter, and a pain pump may be placed.

Postoperative Instructions

To encourage a predictable recovery, the surgeon must carefully instruct the patient in all aspects of the postoperative course:

The minimum time off work will be 2 weeks; the time away from exercise and heavy lifting will be at least 6 weeks.

The patient should be assisted to ambulate early, and calf exercises and spirometry exercises should be conducted regularly.

A full diet should gradually be introduced over several days.

Drains and sutures will usually be removed within several to 10 days.

The timeline of healing includes bruising for at least 2 to 3 weeks and swelling that will resolve over a minimum of 3 to 6 months.

Preoperative Planning

LORNE K. ROSENFELD

Decision-Making

Before the first stroke of the marking pen is made, the entire anterior trunk must be analyzed and staged plans made to address all areas of deformity. The key to designing a comprehensive repair is to envision the entire trunk as composed of aesthetic units rather than focusing solely on the obvious lower abdominal excess:

1. The hips and thighs: Is there extra fat or skin? If there are discrete noncellulite fat deposits with nominal excess skin, concomitant liposuction is wise. How-

ever, if skin traction at the hip effects a good contour change at the thigh, then one needs to consider a high lateral tension procedure.

2. The lower rib cage and upper abdomen: Is there significant redundant skin? It is unlikely to change after an HLTA; a reverse abdominoplasty at a later stage or an initial fleur-de-lis–type abdominoplasty would best treat this difficult zone.
3. The epigastric and supraumbilical abdomen: Is there a prominent subcutaneous layer of fat? If so, the surgeon should consider a second-stage aggressive liposuction procedure to treat this deformity definitively and with greater safety.
4. The pubis: Is it redundant and/or full? If so, liposuction of the area, with or without excision of excess pubis, will prevent a residual distracting deformity in this area.
5. The waist: Is it square? Additional fascial sutures and liposuction in the area could “nip in” this area. If this area harbors large skin excess, a fleur-de-lis approach should be considered.
6. The breasts: Are they in need of rejuvenation as well? This deformity should be broached at this time, because the breasts must be considered an aesthetic unit if a complete repair is to be planned. In addition, any redundant upper abdominal skin can be efficiently resected at a later stage through the breast incisions as part of a reverse abdominoplasty.
7. The skin: Are there subcostal or midline scars? In the patient with significant redundancy, the surgeon should seriously consider a fleur-de-lis approach that could excise most if not all of these scars and obviate potential ischemia concerns.

Once all components of the abdomen and its “environs” have been evaluated, the surgery can be definitively mapped out: A number of surgical approaches are available to treat abdominal deformities. These range from liposuction only to full abdominoplasty with fascial plication. The decision is based on evaluation of the abdominal skin, subcutaneous fat, and underlying fascia. The patient’s desires must also be taken into account: Is she seeking recontouring to look better in her clothing, or is she looking for recontouring and skin tightening so that she can look good in a two-piece bikini?

Liposuction

The best candidates for liposuction are nulliparous women with a modest amount of excess fat, tight abdominal musculature, no hernias, and tight skin of normal elasticity. Some women who have had children with minimal to modest loss of skin elasticity and no diastasis may also be candidates for liposuction if they understand that their skin quality will not be improved but their contour will be greatly enhanced, especially when they are fully clothed. These women should understand and accept this tradeoff for a less-invasive procedure.

Traditional Abdominoplasty

Patients who have excess skin above and below the umbilicus, periumbilical hooding, fat excess, and diastasis or abdominal wall hernias are appropriate candidates for traditional abdominoplasty. Traditional skin excision and more extensive skin excision is required to deal with the supraumbilical skin excess. These patients should anticipate improvement of their appearance in and out of their clothes.

Limited Abdominoplasty

Patients with nominal excess skin above and limited excess skin below the umbilicus are reasonable candidates for a more limited abdominoplasty. This approach is most conducive in a patient with a high-riding umbilicus. The patient may have a diastasis or even an umbilical hernia, which can be repaired through the limited approach. The effect on umbilical position is an important determining factor to candidacy for this approach. The limited skin incision combined with musculo-fascial tightening with liposuction above and below the umbilicus will enhance the patient's appearance in and out of her clothing.

High Lateral Tension Abdominoplasty

The "pure" Lockwood type of abdominoplasty is effective for patients with excess skin at the abdomen, lateral hip and thigh, pubis, and even the anteromedial thigh. If there is a significant amount of excess skin superolaterally, then either conversion to a fleur-de-lis approach or a plan for a second-stage reverse abdominoplasty should be considered. A concomitant reverse abdominoplasty is not recommended, because the intervening band of blood supply may not be enough to sustain the flaps.

Fleur-de-Lis Abdominoplasty

The fleur-de-lis abdominoplasty is appropriate for patients who require more aggressive treatment for excess skin throughout the abdomen and trunk, particularly at the upper pole of the abdomen and lower chest and back as well as at the waist, hips, and thighs. The patient must accept the tradeoff of a full midline scar for a more complete skin resection. This approach is also efficacious in a patient with abdominal scars that could otherwise compromise the blood supply of a more traditional abdominoplasty.

Reverse Abdominoplasty

The reverse abdominoplasty is particularly relevant in patients with primarily or residual excess upper abdominal skin. This approach can be very synergistic when combined with a Wise pattern type of breast surgery.

OPERATIVE APPROACHES

Liposuction

GILBERT P. GRADINGER

Some nonobese women who have a protuberant lower abdomen without excess skin present with good skin tone, excess lower abdominal fat, and some muscle laxity. Typically, liposuction alone can improve their contour.

Use of a tumescent technique (usually injection of 500 to 1000 ml Ringer's lactate with 50 ml of 1% lidocaine and 1 ml of 1:1000 epinephrine) enables the surgeon to suction fat with very little blood loss and a nice improvement in abdominal wall contour.

Although liposuction will never improve stretch marks, abdominal wall contour can be improved in some patients who do not want any form of abdominoplasty, as can be seen in this patient with poor skin tone and stretch marks.

Traditional Abdominoplasty

GILBERT P. GRADINGER

Anterior abdominal dermolipectomy, with or without liposuction, constitutes traditional or classic abdominoplasty, which has two significant variations, depending on the management of the umbilicus. Dermolipectomy of the anterior abdominal wall removes excess skin and fat, primarily in the vertical direction. The repair results in tightening and flattening of the abdominal wall. The additional surgical component, fascial tightening, further flattens and contours through horizontal tension narrowing the waistline. Variations on the traditional abdominoplasty include lower abdominoplasty, HLTA, and fleur-de-lis abdominoplasty.

Markings

The patient is examined and marked for surgery the day before the procedure. She has been advised to wear her usual style of underpants or swimsuit bottom (her choice), so that the garment will conceal the planned incision and resultant scar. The practice of marking the patient in the office the afternoon before the day of surgery has served my patients and me well.

An office nurse is present and assists in making the patient feel more comfortable in this private setting, in contrast to the preoperative holding area. The patient is able to see the markings in the office, ask questions, and offer an opinion (particularly in liposuction marking). Thus she will have a better understanding of the location of incisions and resultant scars.

Planning is vital to successful surgery, and it can be done more accurately in a controlled situation. Photography is achieved with precise consistency of positioning, lighting, and background. I do not have to arrive in the preoperative holding area to arouse a medicated patient or request that she not be medicated until I have completed the markings.

Surgical marking is performed with the patient standing. The excess skin and fat to be excised are usually from the umbilicus to the pubis vertically and from one anterior superior iliac spine to the other horizontally. The maximum excision is in the midline, and it tapers laterally. The surgeon makes a clinical judgment as to whether supraumbilical skin will reach to the pubis after removal of the intervening skin. This can be done by grasping the tissue and bringing the proposed midline points together. The surgeon should be alert for patients with a greater-than-usual distance from umbilicus to pubis and a short distance from the xyphoid to the umbilicus.

The patient should urinate before leaving the preoperative holding area for the operating room. By going to surgery with an empty bladder, the patient avoids the need for a Foley catheter. Operating time is usually less than 2 hours. The patient will have recovered well enough from anesthesia to void spontaneously. Therefore the risks associated with an indwelling catheter are eliminated.

The periumbilical markings are made with the patient supine on the operating table, as is the vertical midline mark from the xyphoid process to the umbilicus. The estimated location of the new umbilical skin site is marked.

Operative Technique

After general anesthesia has been induced and the patient has been prepared and draped, the 3, 6, 9, and 12 o'clock positions of the umbilicus are needle-tattooed and the circumferential incision is made. Two dots are tattooed at the 12 o'clock position to prevent accidental rotation of the umbilicus at the time of repair.

The umbilical stalk is dissected to the level of the anterior abdominal fascia.

The skin and subcutaneous flap are dissected from the pubic/inguinal region cephalad at the level of the anterior abdominal wall fascia. Dissection continues cephalad to the lower border of the rib cage laterally and the xyphoid centrally.

The tissue excised is a full-thickness skin and subcutaneous block including subscarpal fat cephalad to the skin excision.

The elevated fat flap from which fat deep to Scarpa's fascia has been excised is shown. Dissection and hemostasis are achieved with an electrosurgical unit.

The extent of anterior abdominal wall midline fascial laxity is tested with forceps and the width of laxity marked for repair.

The laxity and underlying diastasis are repaired by a running absorbable monofilament suture (for example, Monocryl) from the xyphoid to the umbilicus (and the umbilicus to the pubis). Liposuction is performed, then the wound is irrigated with saline solution and hemostasis is ensured. Jackson-Pratt drains (No. 7) are inserted in each side through separate incisions in the pubic region.

The lowest midline point on the flap is advanced inferiorly to be sutured to the midline pubic skin. Subcutaneous fat is retained at the margin in the midline; this is important for skin circulation.

The 1-inch-long horizontal skin incision is marked in the midline directly over the umbilicus. It is anticipated that the umbilicus will again be vertically oriented after healing, because the tension placed on the flap by the closure will convert the horizontal opening into a vertical one.

The umbilicus is delivered through this incision and sutured at the 12, 3, 6, and 9 o'clock positions with one-half dermal (on the skin side) vertical mattress sutures of 5-0 nylon. The circumumbilical repair is completed with a running subcuticular 4-0 Vicryl suture.

The wound is closed in two layers (Scarpa's fascia and subcuticular) using 4-0 Vicryl sutures. It will be obvious that the lower incision is longer than the upper one; it is more curvilinear, whereas the upper incision is straighter. Closing these incisions of unequal lengths is not a problem because of the tension and stretching of skin in the flap, which allows good approximation.

Postoperative Care

Fine mesh, nonadhering gauze and layered 4×4 sponges, ABD pads, and an abdominal binder (three panels, not four, so that respiration is not restricted postoperatively) are used for dressing. The patient is placed in bed with the head, knees, and feet elevated. Intermittent compression stockings, full leg length, are put on the patient in the operating room before surgery; these are activated throughout surgery, in the recovery room, and in the patient's hospital room postoperatively until she is fully ambulatory, at which time full-length support hose are used and continued for 3 weeks after discharge. Surgery is performed either on an outpatient basis, as was done in the patient described in this sequence, or with a 1-night hospital stay. Antibiotics are administered intravenously at the beginning of the surgical procedure and are not used again unless there is a problem postoperatively.

Results

In this photograph of the patient's appearance on postoperative day 1, the patient is erect and drains are in place. Drains were removed on postoperative day 3, when drainage was less than 30 ml per 24 hours.

Patients often ask how the benefits of abdominoplasty would be affected by future pregnancy and childbirth. To my knowledge, this is the only patient in my practice who had a child after abdominoplasty. In this instance, because she controlled her weight and exercised during and after the pregnancy, the benefits of the abdominoplasty persisted. (Obviously, one needs to be careful in drawing conclusions based on a single case.)

The patient is shown preoperatively, 1 day postoperatively, and 1 year postoperatively in all three views. Note the shape of the umbilicus in the three anteroposterior photographs.

The scar is seen and concealed at 2 years postoperatively.

The patient is shown 3 years postoperatively, 1 year later when she is 6 months pregnant, and 7 months after that (4 months after vaginal delivery of a 7-pound, 2-ounce boy).

Another patient is shown to demonstrate the dramatic improvement achieved in abdominal flattening and waist contouring.

This patient's preoperative markings and tissue specimen demonstrate the extensive removal of fat deep to Scarpa's fascia. This fat excision, in my opinion, is a safer way of thinning the upper flap compared with suctioning, because it preserves the blood supply to the skin through the subcutaneous fat that is superficial to Scarpa's fascia.

Limited Abdominoplasty

GILBERT P. GRADINGER

In some patients it is not feasible to remove all of the skin between the umbilicus and the pubic area: a patient who has a relatively high umbilicus, and a patient who has a low suprapubic scar that dictates where the lower incision should be placed. Both factors may coexist in some patients.

This patient had a low surgical scar; the distance from the scar to her umbilicus was 16.5 cm, approximately the same distance as from her xyphoid to the umbilicus. To reach the pubis, the skin of the upper abdomen would have to be stretched to double its normal length.

Operative Technique

The abdominoplasty was modified, with more-conservative excision of skin and fat, and instead of leaving the umbilicus attached to the abdominal wall, it remained part of the flap—its stalk having been transected at the level of the anterior abdominal wall fascia (demonstrated with the surgeon's hand interposed between the flap and the fascia).

The umbilical fascial defect and diastasis were identified and sutured.

The flap was advanced inferiorly carrying the umbilicus, and the incision was sutured. The umbilicus can be seen to be lower on the abdominal wall than it was preoperatively. Drains have been placed and the surgical specimen is seen.

The patient is shown 18 months postoperatively. Because of the tension on the flap created by the closure, the umbilicus is stretched; it is more vertical than it was preoperatively. Unfortunately, the result is compromised by the presence of “dog-ears” (faulty surgical technique). This complication could have been avoided if suturing had been begun at the lateral ends of the incision instead of medially.

Comprehensive Abdominoplasty: High Lateral Tension Abdominoplasty With Complementary Fleur-de-Lis and Reverse Techniques

LORNE K. ROSENFELD

83-1 Comprehensive
abdominoplasty

The abdominoplasty can be deceptively easy to perform yet maddeningly inconsistent in its results. The plastic surgeon is challenged to excise all the excess anterior trunk skin and fat through the shortest possible incision and to ensure optimal healing with an inconspicuous scar. To begin to rise to this challenge requires one to become a student of the abdominoplasty. By continuously honing one's surgical planning and execution, a more balanced technique can be realized that is both reliably safe and aesthetically successful. The high lateral tension abdominoplasty, with some "2.0" modifications, is such a technique.

Traditionally, the primary goal of any abdominoplasty has always been to excise the central lower abdominal excess skin or pannus and plicate the abdominal fascia through a suprapubic incision. Unfortunately, this traditional abdominoplasty may often fall short of this goal: a scar that may ride too high; persistent skin and lipodystrophy at the pubis, thighs, flanks, and hips; and a consistent incidence of mid-line skin necrosis or wound dehiscence.

The HLTA addresses these shortfalls. It may be defined as a more complete treatment of the lower trunk aesthetic unit from the abdomen to the pubis, hips, and thighs, with a greater overall aesthetic result as well as a greater margin of vascular safety. What follows outlines the techniques and tools to accomplish these superior results safely and consistently.

Evolution of the Modern Abdominoplasty

The abdominoplasty technique has evolved significantly over the last four decades. The modern abdominoplasty was born in South America in the 1960s. The basic surgical tenets have always been to conduct a rectus plication, with maximal excision of the central skin excess by extensive undermining of the entire abdominal wall. The closure is often under some tension and is therefore of necessity conducted with the patient in significant flexion. When liposuction was introduced in the 1980s, it soon became apparent that blithely and aggressively adding this modality to the abdominoplasty led to an unacceptable incidence of flap ischemia and skin necrosis. Liposuction then evolved into a more conservative adjuvant treatment.

Although there were indeed fewer physiologic problems with this technique, the aesthetic results were once again more constrained.

Then in the early 1990s Lockwood published a series of seminal articles that single-handedly changed the tack of the abdominoplasty technique. Based on his extensive experience with body-contouring surgery, he decisively demonstrated and definitively modified the surgical principles of abdominoplasty and reported greater safety and improved aesthetics. He enumerated several surgical tenets that were in many ways diametrically opposed to those of the classic or traditional abdominoplasty: the undermining of the central skin flap only to facilitate plication and *discontinuous dissection elsewhere* (to enhance vascularity and allow *judicious* concomitant liposuction) and the *initial* resection of the *lateral* excess skin, with more-conservative resection of the central skin flap to accomplish a more complete and natural repair, and the use of a planned and controlled *high-tension closure*, with diligent use of the underlying superficial fascial system. Thus was born the high lateral tension abdominoplasty.

The High Lateral Tension Abdominoplasty: A “2.0” Version

For a result to be called truly successful, three strict standards must be balanced equally: the case has to demonstrate the greatest degree of *safety* (zero tolerance for complications), with the maximal *aesthetic* result (correction of all “deformities”), and a *consistent* reliability (regardless of patient presentation). As a result, several important expanded principles of the high lateral tension abdominoplasty validate this 2.0 advancement.

The surgeon performing an HTLA procedure should not slavishly follow the otherwise arbitrary mandate that all the skin between the pubis and the umbilicus must be excised. This approach will only truly work in a patient with an enormous pannus. Otherwise, the excisional marking must be placed above the pubic hairline to accomplish closure of the wound, often with an overly tight closure. This approach may result in an excessively high scar and superiorly retracted pubis, an unnaturally flat hypogastrium, and, more seriously, an exaggerated rate of wound dehiscence and skin necrosis. Instead, any redundant pubis should be corrected with excision, rather than be used to help close an overly tight suprapubic wound, as is often the case with a traditional abdominoplasty. The pubis is then closed under no tension and rests in a lower, more inconspicuous location. As a result, it is most often necessary to close the original umbilical site, since all the skin between the pubis and the umbilicus may not be excised. The surgeon must resist the temptation to remove even a few centimeters of intervening abdominal skin for fear of recreating the usual overly tight closure. This small scar is a reasonable tradeoff when compared with the traditional closure, which can lead to complications.

Any abdominoplasty should consider not only what is above the future incision (the traditional pannus) but also what is below; that is, the pubic excess, anterolateral and medial thigh redundancy, and buttocks laxity. Otherwise, the tissues below the incision may appear distractingly untreated postoperatively, and the full effect of the HTLA may not be realized. This tenet underlines one of the greatest benefits to the HTLA that is not usually considered possible with the traditional abdominoplasty: one can realize a true “body lift” effect through an anterior incision only. Therefore this procedure is really simply a “tension abdominoplasty,” with sequential tension placed from lateral to medial.

This notwithstanding, *the goal of the design and placement of the future scar should primarily be to hide the scar.* Lockwood originally described a very high (“French-cut”) lateral closure, probably because that style of clothing was more fashionable at the time, and a more oblique vector of pull does more efficiently treat the upper abdominal excess, as described above. However, considering how fashion changes, and that a hidden scar will usually trump some residual excess skin, the surgeon should mark the patient *within* the margins of her preferred clothing. This becomes particularly relevant when the patient favors low-cut jeans.

The *location and extent of the remaining subcutaneous fat* must be evaluated and respected. This assessment represents an age-old plastic surgical battle between “beauty and blood.” That is, at what cost to the blood supply does the surgeon attempt to remove all remaining excess subcutaneous fat? Lockwood originally described a reasonable detente: liposuction should only be conducted beneath tissues that have not been undermined. However, most recently, the pendulum has swung back: published articles are once again advocating more aggressive full truncal lipo-

suction at the time of the abdominoplasty. This recommendation is predicated on the idea that if one follows the original Lockwood admonition to restrain the flap dissection only as much as needed to conduct a fascial plication, enough perforators will be preserved to allow for this aggressive liposuction. However, as stated earlier, Lockwood also warned that despite this conservative undermining, liposuction of the remaining central skin flap should not be done for fear of skin flap necrosis. And realistically, some of these same precious perforators are often sacrificed to repair the more protuberant abdomen. This principle should be respected when one considers Lockwood's extensive experience.

If the premise is to preserve the central flap's blood supply by undermining only centrally to allow fascial plication, it may indeed be self-defeating to then disrupt the very same flap with liposuction. Ironically, the only patients who might be candidates for such an aggressive approach would be those without a significant amount of fat in the first place; that is, patients with a low BMI. Otherwise, the usual abdominoplasty patients with higher BMIs could undergo liposuction at the waist and hip rolls, but a *second-stage* liposuction 6 months to a year later should be planned for the central skin flap. Only then can a zero tolerance for skin flap necrosis and dehiscence be realized.

It has always been important to evaluate *the magnitude of excess skin to be excised*. But to actually design the most "efficient" length and direction of the incision, *it is critical that the extent and orientation of the skin left behind also be assessed*. At once, the surgeon must ensure that the remaining skin is both sufficient to close the defect and efficiently relieved of its own redundancy. This principle may be applied to both the central and lateral closure. Specifically, laterally, the excess skin at the hip and thigh is often neglected by the traditional abdominoplasty. This primarily *obliquely* oriented excess tissue is efficiently removed through the *oblique* incision/vector of the HLTA. Centrally the superfluous skin at the epigastrium is in fact a primarily *horizontal* excess (that has migrated from the chest) that can neither be efficiently removed nor "used" to close a lower abdominal defect through a *horizontal* incision. Therein lies the potential flaw in the traditional abdominoplasty as well as the efficacy of the high lateral tension technique. An incongruent consequence may occur: the wound closure may be too tight despite the apparent epigastric redundancy, which can in turn be left behind, and the lateral excess cannot be effectively treated because the remaining abdominal flap has been primarily used for the central closure. To reconcile this paradox, *less skin should be excised centrally and more skin must be removed laterally* through an HLTA-oriented incision and repair. These concepts are illustrated on p. 2970: Using "vector analysis," the lateral tissue above and below the incision is redundant in a more oblique vector and so should be removed through an opposing oblique incision. Serendipitously, this matches the relative direction of the desired HLTA lateral scar placement. In addition, this oblique vector also treats the more horizontal excess in the epigastrium. Similarly, this same

concept can be applied to the fleur-de-lis and reverse abdominoplasties. *Thus the more a procedure follows the vectors of excess of both what is taken and what remains, the more efficient the treatment of all redundant skin.*

Equally, the abdominoplasty should not only consider the obvious suprapubic pannus, but also *the deformity of excess tissue in the epigastric/midline, subcostal, and lateral chest*—zones that have generally been neglected by the modern abdominoplasty. This problem is significantly exaggerated in post-weight loss patients compared with average abdominoplasty candidates. However, the challenge cannot be ignored, and indeed, experience with post-weight loss patients brings significant clarity and urgency to addressing the issues. In fact, the good corrective techniques originally described many years ago have been equally neglected: the fleur-de-lis and reverse abdominoplasties. The solution is to reharness these procedures as a *complement* to the high lateral tension approach and in so doing, forge a more *comprehensive abdominoplasty*. Then, the inclusion of a vertical incision to the high lateral tension procedure makes a better fleur-de-lis abdominoplasty, and the staged application of a full submammary incision to the results of the HLTA creates a more powerful use of the “reverse” abdominoplasty. In effect, the abdominoplasty becomes a true rejuvenation procedure of the *entire* abdominal aesthetic unit.

This potential marriage of procedures is illustrated above. The vectors of skin laxity at the abdomen are marked and applied in each complementary variation of abdominoplasty. As one can see, *the more a procedure follows the vectors of excess, the more efficient the excision of redundant skin.* In turn, *the more vectors of excess that are addressed by surgery, the better the results.* Thus by building a suitable procedure using these harmonizing techniques, a more comprehensive abdominoplasty emerges.

To summarize, the primary advantage of these variations on the theme is the more inclusive repair of the entire anterior trunk. These procedures are entirely predicated

on careful discontinuous undermining and proper use of the superficial fascial system. Then one is assured of viable flaps and a secure and predictable final closure and scar.

However, the more extensive surgeries can be a disadvantage. These cases require more surgical time, longer and often a greater number of incisions, and planned but nonetheless greater closure tension, with the attendant increased risk of dehiscence.

Traditionally, the primary goal of any abdominoplasty has been to excise the suprapubic pannus and plicate the abdominal fascia through a relatively hidden incision. Unfortunately, this established abdominoplasty can fall short of this goal: a scar riding too high; persistent skin and subcutaneous lipodystrophy in the midline, thighs, flanks, and hips; and midline skin necrosis.

The comprehensive abdominoplasty addresses these shortfalls. It may be defined as a more complete treatment of the entire anterior trunk aesthetic unit from the submammary and lateral chest area to the pubic, thigh, and buttock zones, with a greater overall aesthetic result and margin of vascular safety.

Pertinent Anatomy

The general abdominal anatomy is well described in the section of this chapter by Dr. Farzad Nahai. Therefore I will highlight the specific anatomy most relevant to the understanding and application of this high lateral tension abdominoplasty. There are three critical anatomic points that should be understood and respected when planning and performing the HLTA:

1. The superficial fascial system: this layer must be identified and utilized fully to harness the full lift that this technique can provide and to prevent wound dehiscence.
2. The perforator blood supply: the abdominal flap's viability is predicated on the preservation of as many fascial perforators as possible.
3. The zones of adherence: these various points of skin attachment must be released, at least bluntly, to realize the maximum "translation" of pull of the remaining skin envelope, particularly at the anterolateral thigh region. There is often what may be called a "waist band of adherence" at the patient's midsection that can significantly inhibit this same translation.

Markings

The marking starts and is entirely driven by the delineation of the final position of the scar. The 2.0 modification ensures that the scar will rest within the patient's underclothes. The next marking outlines the extent of excess skin *below* the incision (if any) relative to the final scar, and the final marking is simply an estimate of the excess skin *above* the incision.

Marking is performed with the patient in an upright position against a wall so that she can be supported as necessary during the “tension” marking.

The placement and length of the lateral scar are discussed with the patient; this decision should be made by balancing the merits of the best surgical approach to treat the problem with the patient's preferences in clothing styles. The surgeon must consider the planned procedure with the patient wearing his or her most revealing clothing: underwear, a one- or two-piece swimsuit, and low-cut jeans. The incision will rise or fall at the hip markings, depending on the style of clothing.

Location of the Eventual Scar

Boundary marking: First, the outline of the patient's preferred clothing is drawn (underwear, low-cut jeans, or a swimsuit).

Suprapubic marking: Next a point 6.5 to 7.5 cm measured superiorly from the upper incisura of the vagina or base of the penis is marked on the skin as it rests.

Lateral limit marking: A vertical line is marked on each side at the lateralmost extent of the excess skin (pannus).

Closure marking: Finally, the pen is moved superolaterally from this suprapubic mark on each side to meet somewhere along the lateral mark, always staying within the borders of the outlined clothing. This line usually rests between the natural inguinal and abdominal wall gullies. NOTE: One can measure the distance between the fixed point (anterior superior iliac spine) and this marking to aid in an intraoperative cross-check and adjustment of the final resting place of the closure.

To ensure a harmonious scar, particularly in a very “ptotic” patient, it is useful to extend the marking to include the design of a posterior body lift that may be planned or desired in the future.

Defining the Lower Margin of Excision

The marking pen is placed over the line of future closure, and this position is maintained this while pulling the excess skin is vigorously pulled upward until taut (this is the “tension” in the HLTA); then the surgeon marks the skin that is now below the tip of the pen.

This maneuver is performed across the width of the abdomen as needed to define the lower incision. NOTE: Because the maneuver can and should be quite forceful, it is helpful to have the patient lean against a wall during the marking.

Estimating the Upper Margin of Excision

The excess skin is pinched with the thumb on the lower incision line and the fingers at the superior extent of the excess, while maintaining the premarked final closure line visible at the middle of the skin roll. Marking begins laterally and extends medially. The resultant line will usually rest several centimeters above the level of the umbilicus laterally and a few centimeters below the umbilicus centrally.

Deciding How to Treat the Umbilicus

Depending on the patient's body habitus, the umbilicus should be about 9 to 12 cm above the superior margin of the pubis. The umbilicus should rest slightly above the latitude of the superior margin of the iliac crests. However, in the final analysis, as with many challenges in plastic surgery, a critical eye should ultimately drive the surgeon's decision.

The treatment of the umbilicus is determined by two factors: The amount of *excess* skin above and below the umbilicus and the *location* of the umbilicus in conjunction with the *length* of the abdomen and waist.

If there is no excess above and mild excess below, the excision may be conducted with the umbilicus left intact, as a mini-abdominoplasty.

If there is moderate excess below the umbilicus and little to no excess above, and the umbilicus appears high-riding on the abdomen, it can be maintained in situ and stretched on its stalk for a couple of centimeters.

If there is moderate excess of skin below and above and the umbilicus is relatively high-riding, the umbilicus may be “floated” inferiorly with release of its stalk, again for a few centimeters.

If there is a large excess, above and/or below the umbilicus, then it must be circumscribed and translocated.

The areas for liposuction are marked as needed, including the hips, waist, pubis, and thighs. Finally, the surgeon checks the surgical plan markings and reconciles expectations by simply instructing the patient to reproduce the desired result by performing an “examination room lift” (*right*). This maneuver is particularly valuable with a weight-loss or postpartum patient.

Green line: estimated upper incision

Red line: planned location of final closure

Blue line: defined lower incision

The final markings are shown above.

Operative Technique

The patient is positioned supine on a warmer, an antiembolic compression device is applied, and a Foley catheter is usually inserted. With a needle and dye, the quadrants of the umbilicus are marked; the center point of the pubis and the estimated location of the future umbilical site are also marked.

The lower markings are incised and the skin flap is elevated off the deep fascia, just wide enough to allow plication of the rectus fascia. One should also attempt to leave behind as much of the fascial and particularly inguinal “lymphatic” tissue as possible.

Plication of the midline abdominal wall fascia is then accomplished using a heavy stitch (0 or 1-0 PDS) in a running pattern. The surgeon should try to avoid capturing any of the underlying muscle. A second running suture is performed to reinforce and allow for further plication of the fascia as necessary. Additional plication may be carried out in an oblique or horizontal vector at the anterolateral abdominal wall to narrow the waist and further flatten the abdominal wall.

Further mobilization of the flap and release of the skin flap adhesions may be conducted cautiously beyond the midline. The guiding principle is to preserve as many perforators as possible. The surgeon could use either a measured, vertically oriented

spreading of a large Mayo-like scissors or a gentle penetration with one or more fingers, oversized suction cannula, or, as I prefer, a Lockwood underminer cannula (Byron Medical, Tucson, AZ).

With a Lockwood abdominal demarcator (Byron Medical), a modified D'Assumpção-type clamp, the excess skin is marked for resection. This must be performed from the lateral aspect of the abdomen toward the center to truly carry out a high lateral tension resection. As an insurance maneuver, the preoperatively determined desired distance between the anterior superior iliac spine (ASIS) and the future closure can be checked intraoperatively and appropriate adjustments made (and more or less skin removed).

First, Kocher clamps are placed on the upper flap and the skin clamp tongs are secured into the skin edge of the lower margin of the incision. Then with simultaneous pulling of the Kocher clamps on the flap and the pushing of the Lockwood instrument at the lower incision, the excess skin is marked. The vector of pull of the flap is decidedly inferior and lateral.

The tip of the demarcator is pulled back a centimeter or so and the incision is skived to maintain a little more skin than subcutaneous tissue. In this way, when the deep closure is performed, the tension will be more on the fascia, and the skin will “heap up,” with virtually no wound tension.

An effort should be made to avoid closure over the ASIS itself to prevent additional tension to the wound. And contrary to the traditional approach, it is not necessary or desirable to place the operating table in a “lawn chair” position, because the Lockwood technique does not mandate the excision of all the infraumbilical skin and thus excess tension on the suprapubic closure and the resulting side effects are prevented.

As planned, not all the skin between the umbilicus and the pubis is usually excised, so depending on the amount of skin resection, the umbilicus can be stretched in place, allowed to float, or circumscribed and translocated with the original umbilical site closed vertically when necessary. As needed, a triangular segment of mons pubis can be excised if there is significant horizontal excess.

Once skin is excised and tacking sutures are placed, tumescent fluid is suffused and liposuction conducted at the waist, hips rolls, pubis, and thighs as planned. The areas that deliver the greatest reward, yet are most often neglected, are the waist and the pubis.

The new umbilical site, when needed, is then incised in a *vertical* direction, since this wound will be pulled open to an appropriate shape with the significant lateral pull of the high-tension approach. A small elliptical excision of skin on either side of the vertical incision may be conducted as needed to increase the width of the umbilicus.

Three or four 10 mm flat drains are placed before closure, along with a bupivacaine catheter for postoperative pain control.

Bupivacaine may also be injected directly into the fascia for immediate postoperative relief. Using 1-0 or 0 PDS suture, the superficial fascial system is reapproximated every few centimeters. This is probably one of the most important steps in the whole operation. *The more confident one is of the fascial closure, the more definitive and aggressive one can be of the skin traction/resection.* The final closure is then made with 2-0 Vicryl for deep dermis and 3-0 Monocryl for superficial dermis.

The closure should have a decidedly rolled border, indicating no skin tension. Shortened Steri-Strips (to prevent edema-induced blisters) are placed. Fluffs are applied along with an abdominal binder to complete the dressing.

Postoperative Care

Immediately after surgery, the patient is placed on a hospital bed in a “lawn chair” position, with the Foley catheter in place. The patient is transferred to an outpatient facility for 1 to 3 nights to ensure proper pain control and hydration, assistance with ambulation, showering, and so on. A spirometer, antiembolic pumps, and TED-like hose are all ordered for continuous use until the patient is ambulating regularly. The Foley catheter is usually removed at that time. Patients are given stool softeners once they are taking food by mouth. The pain-control catheter is removed in 4 or 5 days. Drains are left in place for 5 to 14 days, depending on the amount of drainage. The patient wears a Velcro binder as much as possible for up to 2 weeks; then the patient is encouraged to wear some form of commercial girdle-type compression undergarment for an additional 6 weeks.

Complications

The entire purpose of the HLTA is to deliver the optimal correction with the lowest complication rate. Just as with Lockwood's original opus on the subject, the 2.0 upgraded version described here is predicated on a zero tolerance for complications. As well, many of these outcomes are not really complications but rather planned trade-offs for better or safer results. When a patient is informed of an expected residual deformity, he or she will then consider it as part of the surgical plan rather than as a complication; that is, the patient will then appreciate a secondary surgery as a stage rather than a revision. Otherwise, complications may include aesthetic mistakes, which may be irreversible, as well as physiologic misadventures, which can be devastating. These are discussed next, with a brief description of methods of prevention and treatment.

Aesthetic Complications

Abdominal Scar Too Long

The scar can only be “too long” if the patient was not clearly informed of its often requisite length. The lateral scar is the primary literal footprint of the HLTA; that is, if any tension lifting is attempted at the lateral thigh and hip area, the incision will inevitably be longer. *Therefore the surgeon should critically evaluate this anatomy preoperatively and decide, with the patient's input, whether there is enough laxity to warrant extending the incision.* Otherwise, experience would indicate that as long as a scar is of good quality, corrects the deformities, and, what is most important to the patient, is hidden, the patient will always accept a lengthier repair.

Lateral Scar Too High or Too Low

In general, the greater the excess skin present, the more unpredictable the scar placement can be. This outcome is usually caused by a poor marking design; that is, an overestimation or underestimation of the magnitude of skin redundancy below the incision. There are several ways to avoid this problem, depending on the magnitude of redundant skin:

If there is significant excess below the incision, there is a real danger of unpredictable scar placement (usually riding too high), and during the marking the surgeon must be certain to place the skin on maximum tension and, like any good tailor, measure twice and cut once—that is, recheck the markings and “test” them by having the patient recreate the lift by pulling up the excess tissues to the desired location.

If there is not a notable excess below the incision (usually in the thicker, less mobile skin envelope), the scar could be predictably too low if too much inferior skin is removed. Therefore the surgeon should place the skin on less tension when marking.

Intraoperatively, the preoperative measurement of the distance between the fixed ASIS and the desired level of the final wound may be used as a guide. It is best to be conservative with any additional resection (especially in a more adipose-filled flap), since the thigh skin below may drift inferiorly postoperatively.

Finally, after surgery the surgeon should always critically assess the preoperative markings against the final result to properly hone his or her tailoring techniques.

Pubis Too Tall or Too Short

A pubis with an incongruent height is usually the result of inaccurate estimation of the true redundancy of the pubic area. The surgeon must put the pubis on maximum stretch during marking and leave at least 6.5 cm of pubic height. The pubis can also be too wide, with the tension surgery potentially worsening the aesthetic effect. If necessary to prevent this appearance, a wedge resection of the pubis can be done concurrently or at a later stage. Again, the surgeon should always revisit and the preoperative markings and compare them with the postoperative scar placement.

Poor Umbilical Closure Scar

Poor umbilical closure is often the most feared (more by the surgeon than the patient) but least realized complication. These scars uniformly resolve into short, thin, white lines. Rarely, a steroid injection or revision will be necessary. Even so, as the patient is made aware, this 1-inch scar is a small price to pay for the alternative: a 1½-foot-long abdominoplasty scar that rests too high, pulling the pubis along with it.

Residual Fat at the Suprascar and Central and Superior Abdomen: The Inverted-T

This “complication” is more accurately a deliberate “neglect” of this subcutaneous fat in an effort to preserve the maximum blood supply to the central flap. The surgeon must decide what his or her individual tolerance is for the very real complications that may ensue from an attempt to remove this fat. Otherwise, patients are simply informed that they may be best served with a second-stage, unfettered abdominal liposuction procedure.

Residual Skin at the Upper Abdomen

Residual skin is a complication not really unique to the HLTA. In fact, there is a good argument that because this technique has a more oblique vector of pull, it can efface more of this redundancy. However, the patient with significant excess (a second pannus) should be informed preoperatively of its probable persistence. Only a fleur-de-lis or reverse abdominoplasty can treat this zone definitively and should otherwise be considered in the first place.

Lateral Dog-Ears

The best way to avoid lateral dog-ears is to fully liposuction this area and to intrepidly extend the incision as necessary, particularly the more tension-filled the lift.

Epigastric Recurrent/Residual Protrusion

Because of the more conservative dissection in the upper abdomen with an HLTA, in a patient with a very protuberant abdomen it is possible that a less than complete repair will be performed. Consequently, there can be some degree of epigastric recurrence/residual deformity postoperatively.

Physiologic Complications**Superficial Fascial System Stitch Abscesses**

The stitches used for the tension closure of the fascia are per force of large caliber with abundant knots. Therefore, stitch abscesses may arise postoperatively (surprisingly very late) particularly if permanent suture is used. This problem is far less likely with well-buried, absorbable sutures.

Seroma

Because there is far less dissection and no central liposuction with an HLTA, the annoying problem of seromas should be rare. For the same reason, the idea of flap adhesion stitches is not really applicable to the HLTA. When a seroma does occur, a consistent set of aspirations usually solves the problem within a few weeks. The primary modes of prevention include maintaining the web of lymphatic-containing tissue overlying the fascia and groin when elevating the flap, and placing multiple drains (three or more).

Deep Venous Thrombosis and Pulmonary Embolism

Volumes of analysis and advice have been written on this subject, particularly in the last few years. Clearly, with good patient selection, consistent use of antiembolism pumps, and early mobilization, the incidence of this problem should remain rare. As for chemical prophylaxis, considering the still unsettled status of this approach, the surgeon should always refer to the latest recommendations in the literature.

Skin Necrosis

Skin necrosis is a dreaded complication that can occur if the surgeon pushes the envelope during surgery: the usual culprits are maneuvers of overaggressive flap mobilization in an effort to remove the maximum amount of redundant skin (particularly from the upper half of the abdomen) and excessively zealous flap fat removal (by liposuction or direct excision) to thin the flap as much as possible. Unfortunately, the patients who would need these additional efforts to be taken are often the candidates that present the greatest risk, with high BMIs and massive excess of fat and/or skin. And for the patients who fall in between, there is no accurate selection mechanism to determine who will do well with these more-invasive techniques; therefore surgeons must decide for themselves between “blood and beauty.”

Outcomes

The essential advantage of this technique is the ability to deliver consistently superior and safer results:

The incision is maintained low and hidden within the patient's clothing.

More skin is removed below the incision both laterally (which, in effect, results in a significant "lift" of the anterolateral thighs) and centrally (which promotes a lift of the pubis and anteromedial thighs).

There is little opportunity for flap ischemia because a maximal blood supply is maintained: local perforators are preserved with judicious and discontinuous undermining, and the flap's integrity is respected with restraint of any liposuction or direct fat removal from the flap itself.

There is less tension at the lower central abdomen, resulting in a lower incidence of flap ischemia and a more aesthetically pleasing mild convexity at the hypogastrium.

The excess skin in the horizontal plane of the abdomen, particularly in the upper poles, is more effectively treated with the oblique vector of excision.

Any residual fat, particularly within the abdominal flap itself, can be treated aggressively, with relative impunity, as a second-stage procedure within 6 months to a year of the abdominoplasty.

If there is residual skin resting laterally and posteriorly, this can be addressed at a second-stage procedure with a posterior extension of the abdominal incision for a completion posterior body lift. If there is remaining skin superiorly at the epigastric and subcostal areas, this can also be treated later with either excision through submammary incisions or with a proper reverse abdominoplasty.

If the lateral scar rests slightly outside the patient's preferred clothing, the scar can be easily moved up or down by excising the appropriate amount of skin with the patient under local anesthesia.

Fleur-de-Lis Abdominoplasty

Dellon first popularized the fleur-de-lis technique in 1985. He pointed out that his technique was an extension of Regnault's classic "W" technique. For a longer historical perspective, the fleur-de-lis, as Dellon describes, is really a direct, albeit melded, descendant of the transverse resection technique described by Kelly in 1910 and the vertical resection approach considered by Babcock in 1916.

The basic principle and power behind the fleur-de-lis approach is the ability to definitively excise not only the traditional lower abdominal pannus but also much of the aforementioned redundant upper abdominal tissue. Put another way, this approach realizes a more complete resection of not only the vertical but also the horizontal vector of excess. But it is important to realize that this technique, in contrast to its original description, can now be “supercharged” with the addition of the high lateral tension procedure. The corollary would be that the fleur-de-lis is really an HLTA with the addition of a vertical incision. Thus the fleur-de-lis approach becomes even more potent at correcting the entire abdominal unit. In fact, if a reverse abdominoplasty is also included, either conservatively at the time or in a staged repair, this trio of techniques can make the most complete and impressive correction.

In combination with the high lateral tension technique, the fleur-de-lis can deliver far-reaching effects: in addition to recontouring the upper abdominal zone with direct excision, there is an indirect corset effect of the entire anterolateral chest, the flank, and the back. In fact, this technique can truly address the residual excess skin rolls beyond the pannus, tissues often left untreated by any “regular” abdominoplasty. This advantage is particularly relevant in weight-loss patients. In fact, in these patients, when the surgeon has completed a proper fleur-de-lis resection, the extent of skin resection can expose most of the anterior abdominal wall. Then, dramatically, the peripheral “waistcoat” of skin, lying in the wings, advances to close the defect.

Markings

The basic principle behind the marking of the fleur-de-lis is to evaluate, measure, and mark the horizontal excess independent of the vertical redundancy.

Horizontal marking: With the patient standing, HLTA marking is performed as though it were to be the only procedure planned.

Vertical marking: Next, with the patient supine, the horizontal excess is outlined, again as though it too were the sole surgery to be conducted. The surgeon simply gathers the excess skin with an aggressively wide pinch, marks the margins, and “connects the dots” to realize the vertical marking.

Fleur-de-lis design: With these two apposing markings, the outline of the fleur-de-lis is actually realized. The outline of the intersecting markings is drawn to define the borders of the fleur-de-lis abdominoplasty.

Key point: The pivotal point in the marking is the intersection of the horizontal and vertical markings laterally. This is the best estimation of the location of the wound edge that will ultimately contribute to the inverted-T closure.

Marking test: The excess skin is inverted and the T closure is reproduced. Clearly, the thinner the patient, the easier and more accurate this maneuver will be. The primary objective of this step is to estimate the adequacy of skin for comfortable closure of the T wound. Otherwise, one runs the risk of an excessively tight closure that in turn can lead to problems ranging from an unaesthetic, constricting, high-riding scar and pubis to a devastating skin necrosis.

The final markings are demonstrated. The yellow stars indicate key points marking the tips of the upper flaps and the midline of the suprapubic area. The blue lines are the estimated margins of the fleur-de-lis. The red line is the estimated future site of the scar.

NOTE: The only marking that is actually used in surgery is the lower horizontal line of the HLTA portion of the design, with the rest of the outline acting as guideposts. *The important point is to reserve final judgment regarding the margins of excision until surgery.*

It is very important to *resist marking the superior pole of the incision much above the xiphisternum*, which could cause the final closure to rest between the breasts (and even worse, cause synmastia). That is, one should expect the upper wound to ride up several centimeters with the removal of the heavy abdominal skin and closure of a very wide wound.

Operative Technique

The horizontal and vertical premarked incisions are performed down to the underlying fascia.

The skin flaps are raised cautiously, roughly within the boundaries of the premarked fleur-de-lis template, to preserve the maximum blood supply. Routine abdominal plication is then performed using a 1 or 0 Ethibond type of suture in running, locking fashion.

Then, using a large staple gun or suture and an assistant's help, the surgeon vigorously tailor-tacks the wound by rolling the excess skin below the flaps. *As described previously, it is critical that one begin this tailoring at the suprapubic inverted-T wound to confirm that there is adequate skin for closure.* In effect, this medial commencement of tacking is opposite the traditional Lockwood abdominoplasty in which the excision is estimated and conducted starting laterally.

Once the lower midline closure is estimated, the tacking should continue alternately between the midline toward the xiphisternum and laterally toward the hip, in an at-

tempt to evenly distribute the estimated excision of the excess. As noted earlier, *the surgeon should not tailor-tack the vertical closure superiorly any higher than the xiphisternum* to ensure that the eventual scar lies on the abdomen rather than between the breasts.

The excess skin is then marked at the margins of the tailor-tacking, and the skin is excised through both the vertical and horizontal incisions.

Then the T closure is tacked again to guarantee the adequacy of the skin for closure. At the vertical wound, one can often tailor-tack and excise skin a second time, especially in a patient with very thick or excessive skin. Any remaining skin at the horizontal wound should be removed, as one would with an HLTA using the Lockwood skin clamp.

The closure is then performed in the same manner as in a routine abdominoplasty. An ellipse of the wound margin from each flap is excised at the site of the umbilicus, which is then inset.

With experience, particularly in thinner patients, the surgeon can consider just tailor-tacking the skin at the inverted-T closure only, directly excising the vertical marking and then applying the Lockwood abdominoplasty to the lower excess.

Problems and Complications

The midline scar can extend too far superiorly with the creation of some synmastia unless care is taken to prevent its migration. The primary tactic to avoid this problem is marking the repair deliberately no higher than the xiphisternum and resisting the impulse to chase the excess skin superiorly onto the chest. Also, if the tacking or excision itself is not symmetrical, the vertical scar can be crooked. If this is noted at surgery, an attempt at correction should be made with the necessary skin resection from one side or the other.

Outcomes

The effects of the fleur-de-lis procedure can be the most dramatic of all abdominoplasties: because of the significant recruitment of skin from the lateral trunk, an impressive correction is made at the waist, back, and flank folds. With excision of most of the horizontally redundant skin, particularly at the upper abdomen, the result is clearly more complete. Additionally, because of the wide exposure of the fascia, the abdominal wall deformity can be fully corrected with this technique. This is especially true in the epigastric area, where the repair can be otherwise constrained by the HLTAs narrow tunnel of dissection.

The inverted-T scar heals surprisingly well and becomes a thin white line. Despite the impressive dissection, since primarily all the undermined skin is excised (especially the suprapubic swath of skin), flap ischemia is not a major concern.

Reverse Abdominoplasty

The reverse abdominoplasty was initially described in 1972 by Rebello and Franco in the South American literature. In 1979 Baroudi et al published the first paper in the United States describing the technique in combination with reduction mammoplasty. The reverse abdominoplasty is most efficacious when combined with the other abdominal contouring surgeries already described; that is, the principal indication for reverse abdominoplasty is for cleanup of the residual redundant tissue at the superior abdominal pole after any lower abdominoplasty. This approach is particularly relevant when treating weight-loss patients. Even after proper application of the high lateral tension technique, a reverse abdominoplasty should be anticipated as a second stage. Otherwise, this technique is indicated in the relatively rare patient who presents with skin excess and abdominal protuberance primarily in the upper pole of the abdomen. The utility of this approach is even more compelling if the majority of striae and surgical scars are also principally confined superiorly. A reverse abdominoplasty may be easily married to a Wise pattern breast procedure, since joining the two submammary incisions entails only a few centimeters of additional scar.

Otherwise, with more limited skin excess, direct excision of skin through separate submammary incisions could be considered, particularly in a Wise pattern type of breast surgery.

Markings

The patient is marked in the supine position. The upper margin of the skin resection is outlined initially. The mark should start as far lateral as the excess skin demands, always maintaining the final closure within the bra strap line. The markings then continue along the submammary line, with the two sides meeting at the epigastrium as a V. If there is to be concomitant breast surgery, the mammary markings should be conducted first.

The excess skin at the upper pole of the abdomen is then pinched and pulled superiorly, and an approximate line of redundancy is marked. The extent of excision is guided by observing the maximum tautness of the upper abdominal skin.

The mobility of the inframammary crease is gauged. The more ptotic the breast, the greater the potential inferior displacement of the crease. Thus the crease must be secured at the time of surgery.

The laxity of the umbilicus (the length of its stalk) must also be assessed. The surgeon should attempt to prevent excessive superior displacement of the umbilicus with advancement of the upper flap.

Operative Technique

The upper incision is made and the abdominal flap elevated several inches beyond the skin redundancy. This dissection should be no farther than several centimeters from the umbilicus to block the potential excessive advancement superiorly.

The most critical step in this technique is to define the inframammary fold at the appropriate level so that the skin excision can be more accurately estimated. This is accomplished by first marking the position of the future breast fold on the chest. This should be done with the patient in the upright position to more accurately determine the natural coordinates of the inframammary fold. Otherwise, in the supine position, the fold can rise unnaturally by several centimeters, and the eventual crease could then be sutured too high.

Using Kocher clamps and upward and slightly lateral traction, the surgeon marks the excess and sequentially excises it. As with the abdominoplasty, skin excision is made 1 or 2 cm more proximal to the marked excess point to prevent too much wound tension. The resultant wound can be as much as 6 to 8 inches in height.

The upper abdominal flap is then inset along the now “tamed” inframammary crease. The deep fascia is employed to ensure a secure closure, along the length of the chest using 0 or 1-0 PDS-type suture. As with the abdominoplasty, the suture should be placed in the superficial fascial system approximately 2 cm behind the upper margin of the abdominal flap to ensure a rolled, tension-free skin closure. If a breast lift or reduction is to be performed at the same time, it is preferable to perform the reverse abdominoplasty first. This surgical order creates a solid shelf on which the breast can then be built. Otherwise, a completed breast repair may be compromised by the possible recruitment of some of the lower breast skin when the abdominal flap is inset.

Final closure is similar to that for routine abdominoplasty, using 2-0 Vicryl for the dermis and 3-0 Monocryl for the skin. Two 10 mm drains are placed before closure.

Problems and Complications

With or without a concomitant breast surgery, the sheer heft of the inset abdominal flap can result in some deformation of the breast shape as the tissues relax. The best measure of prevention is to “overengineer” the repair of the abdominal flap to the defined inframammary crease, with an abundance of sutures.

By virtue of the advancement of the upper abdominal flap, the umbilicus can be tethered superiorly. This is particularly true with an umbilicus with a longer stalk. Maneuvers to resist this displacement include reining in such a stalk with direct sutures to the rectus fascia and halting the upper skin flap mobilization several centimeters above the umbilicus.

Outcomes

With an aggressive application of the reverse abdominoplasty technique, there can indeed be a rewarding correction of the disturbingly persistent excess skin at the upper abdomen after a routine abdominoplasty. The central 3 inches of additional scar resting between the breasts heals remarkably well. It can be even more inconspicuous if it is designed to rest inferiorly in a V shape. Postoperatively the breast should remain in a stable, aesthetic position as long as a secure reinsertion of the abdominal flap is performed at the appropriate inframammary level. Some superior advancement of the umbilicus can occur despite all efforts to the contrary.

Results

High Lateral Tension Abdominoplasty

This 46-year-old woman who had had four children requested abdominal repair after her last child was born. A high lateral tension abdominoplasty was performed, along with a mastopexy/augmentation. She is seen 4 years postoperatively, revealing evidence of the significant lateral excision accomplished with this technique, by virtue of the removal of her entire tattoo. The benefits of the HLTA with a more aesthetic waistline and smoother epigastric zone are apparent.

This 46-year-old nulliparous woman was seen after losing 66 kg (145 pounds) following a gastric bypass. She did not want a midline scar, but otherwise desired as much improvement as possible. She underwent a high lateral tension abdominoplasty with liposuction of the hips and lateral thighs. A mastopexy was performed at the same surgery. Note the presence of the supraumbilical line of demarcation carrying the more redundant skin above. Therefore dissection was deliberately discontinuous in this area and the patient was informed of the likelihood of residual epigastric excess postoperatively. She healed without complication. She is seen 8 months postoperatively. Note the correction of the abdominal deformity, even in the epigastric area, because of the oblique vector of its excision. The HLTA's body-lift effect was realized in the anterolateral thigh and buttock areas.

This 57-year-old woman had had two children and had lost close to 45 kg (100 pounds). She underwent an HLTA with liposuction of the hips and thighs and a breast reduction. Note the reconstitution of an aesthetic abdomen and the lifting of the buttocks.

This 43-year-old nulliparous woman lost more than 45 kg (100 pounds) through a gastric bypass procedure. She elected to have an HLTA with liposuction of the hips and thighs. In evidence are the lift and correction of the lateral thigh/buttock region through well-placed scars.

This 39-year-old nulliparous woman had lost 91 kg (200 pounds) through diet and exercise alone. She demonstrated the most desirable skin envelope: thin and mobile. The patient underwent an HLTA using an extended posterior incision so that a more complete excision and lift of the lateral trunk could be achieved, while still properly treating the central tissues. Liposuction of the hips and lateral thighs as well as mastopexy with implantation were also performed.

This 43-year-old nulliparous woman had undergone a bypass procedure and achieved a 66 kg (145-pound) weight loss. She subsequently underwent an HLTA and is seen 9 months postoperatively. The hallmarks of the HLTA effects are evident: the scar rests in a hidden position, the suprapubic skin is not overly tight, and the thigh and hip regions have been lifted. The closeup photo of the thigh reveals the qualitative improvement in the skin extending practically to the knee.

This 50-year-old woman requested rejuvenation of her abdomen; she had had one child. She underwent an HLTA with liposuction of the hips and lateral thighs and augmentation mammoplasty. The pleasing aesthetic of the abdominal repair is realized with a well-placed scar, a not overly tight suprapubic region, and an improved hip-thigh contour. Note the “stealth” skin redundancy, visible when the patient is sitting and bending, and its repair postoperatively. And still there is some residual skin excess in the epigastric area postoperatively.

High Lateral Tension Abdominoplasty With Staged Liposuction

This 35-year-old woman had one child; she desired correction of her abdominal protrusion. She demonstrated a similar excess of skin when bending or sitting. An HLTA was performed with liposuction of the hips and thighs. The benefits of this technique are demonstrated with the return of her prepregnancy contour. As planned, the scar is properly hidden within the patient's underclothes. For safety, a planned second-stage liposuction was performed of the abdominal flap to complete the repair.

Markings for HLTA

Markings for post-HLTA liposuction

This 36-year-old woman, 5 feet 3 inches tall and 70 kg (155 pounds), complained of residual abdominal deformity despite aggressive diet and exercise. She had had three children.

The patient underwent an HLTA with aggressive liposuction of her hips and thighs. Note the relative lift of both the buttocks and thighs. Rather than potentially compromising the blood supply at the first surgery, a secondary liposuction of the abdominal flap was performed instead.

As planned, the very productive, although lengthy, scar is hidden within her underwear.

First Stage: High Lateral Tension Abdominoplasty**Second Stage: Reverse Abdominoplasty With Mastopexy**

This 32-year-old nulliparous woman had undergone a gastric bypass procedure. She had lost approximately 60 kg (132 pounds) and wished to improve the appearance of her anterior trunk, abdomen, and breasts.

A high lateral tension abdominoplasty was performed with a concomitant mastopexy; no implants were placed. In these photographs, taken approximately 15 months post-operatively, improved contours are evident, particularly full correction of the inguinal and hip areas as well as the waist.

The patient then requested correction of the residual redundant tissue at the upper abdomen. Approximately 7 to 8 inches of excess tissue was marked for excision.

A reverse abdominoplasty and synchronous mastopexy were performed. This resulted in a rewarding correction of her upper abdominal deformity. Seen 9 months post-operatively, the appropriate location of the inframammary crease is evident after proper fixation at the time of the abdominoplasty. The photos also demonstrate a slightly overly raised umbilicus, a potential minor stigma of a productive reverse abdominoplasty. As outlined, the surgeon should maintain tissue above the umbilicus undissected and secure the umbilicus to the underlying fascia.

This 43-year-old woman who had had three children underwent a gastric bypass with a resultant loss of 66 kg (145 pounds). She complained of redundant skin throughout her abdomen. Although she would have been an ideal candidate for a fleur-de-lis abdominoplasty, she did not want a midline scar. A high lateral tension abdominoplasty was performed with the ultimate plan of including a reverse abdominoplasty at the time of breast rejuvenation to address the inevitable residual upper abdominal tissue. She is seen approximately 18 months postoperatively. On the oblique views, note the significant reshaping of the hip and lateral thigh contours.

The patient later underwent a reverse abdominoplasty and mastopexy/augmentation to complete her repair. The excess upper abdominal skin remaining after the HLTA is now corrected.

First Stage: High Lateral Tension Abdominoplasty

Second Stage: Reverse Abdominoplasty With Augmentation/Mastopexy

This 46-year-old woman had undergone a gastric bypass procedure. She had an HLTA first and then a staged reverse abdominoplasty for correction of the excess tissue at the upper abdomen and chest. The progressive results are seen.

Fleur-de-Lis Abdominoplasty With High Lateral Tension

This 41-year-old female achieved a 64 kg (140-pound) weight loss from gastric bypass surgery. Her goal was simply to have the abdominal redundancy improved as much as possible. The patient was otherwise very healthy. The massive upper abdominal “second pannus” could only be properly and safely repaired with a fleur-de-lis technique. Significant body contouring was accomplished despite the patient’s thicker habitus. She also underwent a concomitant mastopexy.

This very fit 65-year-old woman desired a better contour with correction of her abdominal redundant skin and protrusion. She had had two children. She elected to have a fleur-de-lis procedure to more fully improve her shape. Note the excess stealth skin that becomes more obvious with change in position or when put on tension. Her aesthetic habitus allowed the full effect of the fleur-de-lis to be expressed with a particularly dramatic improvement in her pubis, waist, upper abdomen, and back folds. In addition, the patient's posture appears to have improved.

This 59-year-old woman underwent a gastric bypass and a subsequent weight loss of more than 45 kg (100 pounds). She requested abdominal correction, and because of the excess skin in the upper poles of the abdomen, we elected to perform a fleur-de-lis abdominoplasty with a proper high lateral tension approach to the lower abdomen.

The results demonstrate the rewarding improvement not only of the abdomen, but also a more far-reaching correction of the waist and back (fleur-de-lis) as well as the thighs and buttocks (HLTA).

This 33-year-old nulliparous woman had undergone a gastric bypass and lost 50 kg (110 pounds). She desired as complete an abdominal recontouring as possible in one stage. Therefore she was very accepting of a fleur-de-lis approach and equally pleased with the relatively full repair of her redundant tissue, as seen here 7 months post-operatively.

Fleur-de-Lis Abdominoplasty With Posterior Body Lift

This 40-year-old nulliparous woman had lost 73 kg (160 pounds) as a result of gastric bypass surgery. A concomitant fleur-de-lis abdominoplasty and posterior body lift were performed. Note the correction of both the abdomen and the surrounding aesthetic units.

First Stage: High Lateral Tension Abdominoplasty With Posterior Body Lift

Second Stage: Reverse Abdominoplasty With Augmentation/Mastopexy

This 53-year-old nulliparous woman had originally lost 50 kg (110 pounds) after a gastric bypass. She was seen 6 months after an HLTA with a posterior body lift and now desired repair of a significant redundancy of the upper abdomen. At the time of the reverse abdominoplasty, a mastopexy with augmentation was also performed. By inseting the abdominal flap before the breast surgery, a definitive breast platform was created. At 4 months postoperatively, note the tight appearance of the upper abdomen. The sequential results are illustrated (see p. 3018).

It is instructive to ask the patient to perform an examination room “nonsurgical lift” (see p. 2975) of the excess skin to demonstrate her goals. As can be seen, the results came very close to meeting those goals.

Fleur-de-Lis Abdominoplasty Using High Lateral Tension and Reverse Abdominoplasty With Augmentation/Mastopexy During One Operative Session

This 35-year-old nulliparous woman was seen after a gastric bypass and subsequent weight loss of 109 kg (240 pounds). She requested both abdominal and breast rejuvenation. As seen in her preoperative photographs, there was a significant amount of excess tissue in the vertical and horizontal dimensions, with cascading skin redundancy at the upper and lower abdomen.

This redundancy was present not only at the abdomen but also extended onto the chest, flanks, and back. She had an upper midline vertical scar; therefore a fleur-de-lis approach was designed. Because breast surgery was to be performed, a conservative reverse abdominoplasty was conducted. This entailed direct resection, without undermining, of the abdominal excess skin through the inframammary incisions. *Therefore the patient essentially underwent all three complementary procedures during one operative session.* The fleur-de-lis surgery was conducted before the breast augmentation/mastopexy to ensure the inset of the upper abdominal flap and the definition of a proper inframammary crease on which the breast could be built.

Her preoperative markings are shown.

The postoperative results at 8 months reveal the impressive, almost circumferential correction. The scar is once again low centrally and hidden throughout. The improvement at the upper chest, back folds, thighs, and waist is evident.

Concluding Thoughts

A well-conceived and well-executed high-tension abdominoplasty, with the addition of the fleur-de-lis or reverse principles, defines a truly comprehensive abdominoplasty, which is a surgical antidote to the shortfalls of more traditional approaches. In essence, comprehensive abdominoplasty is a more complete treatment of the anterior trunk aesthetic unit from the submammary and lateral chest area to the pubic, thigh, and buttock zones, with a greater overall aesthetic result and margin of vascular safety.

Clinical Caveats

Key Principles of the High Lateral Tension Abdominoplasty

The HLTA is driven by the concerted effort to treat not only the tissues above the incision but also those below. This treatment is as much excision of redundancy as it is a far-reaching body lift through a relatively anterior incision. The pubis and anteromedial thighs as well as the hips, anterolateral thighs, and even buttocks can be aesthetically improved by this technique.

This procedure is fundamentally and philosophically different in that the skin is considered more redundant at the lateral trunk than in the midline. Therefore the anterolateral thigh can be more effectively treated. In addition, the redundant upper abdominal skin emanates more from the chest and demonstrates more of a horizontal laxity compared with the vertical laxity of the lower pannus. Thus the relatively oblique pull of the HLTA can more effectively treat this epigastric excess.

This approach, in contradistinction to the traditional abdominoplasty, is not driven by the usually mandatory excision of all the skin between the pubis and umbilicus. Therefore the pubic/median portion of the incision can be naturally lower and more hidden and the closure can be under less tension, improving the chances for healing by first intention and a more natural looking result.

The HLTA often mandates that the incision be longer laterally. However, it is also true that the longer the lateral incision, the better the result. This approach allows the excision of a greater extent of skin, and what is more important, affords an impressive body lift of the surrounding tissues. This balance between scar length and result must be negotiated with the patient.

As a corollary, if there is not a significantly redundant skin envelope at the lateral thigh, the HLTA should be “tempered,” and the scar can and should be shorter.

This technique, although often more effective at treating the upper abdominal skin excess, should be supplemented by a second-stage reverse abdominoplasty procedure when necessary or even “converted” to a fleur-de-lis initially.

The HLTA is predicated on preservation of the flap blood supply first and foremost. As part of this philosophy, for a patient with a medium to high BMI the surgeon should seriously consider a staged liposuction of the central and superior abdominal flap instead of either liposuction or direct excision. Only then can a zero tolerance for skin necrosis truly be honored.

The entire anterior trunk should be considered as one aesthetic unit. Thus not just the traditional lower abdominal pannus is treated but all of the areas surrounding this deformity as well.

Fleur-de-Lis Abdominoplasty

The excess skin (particularly when first applying this technique) should be tailor-tacked in the vertical and horizontal directions to more safely conduct the skin excisions.

Tacking should always be started at the inverted-T junction to ensure that enough skin is preserved for the suprapubic closure.

Surgery beyond the xiphisternum should be avoided to avoid the scar’s riding up between the breasts.

The surgeon should imagine the excision as a fleur-de-lis skin template, never undermining the skin flaps.

Reverse Abdominoplasty

All patients undergoing significant routine abdominoplasties (especially weight-loss patients considering possible breast rejuvenation) should be informed that a reverse abdominoplasty might be desirable at a later time.

The position of the future crease should be accurately determined with the patient in the upright position on the operating table.

The abdominal flap should always be doubly secured to the defined inframammary crease to create a platform on which the breast can rest and the abdominal flap can hang.

The relative mobility of the umbilicus and the extent of excision must be assessed to help determine how much umbilical displacement may occur. The tissue above the umbilicus should be left undissected in an effort to block excessive superior movement.

The abdomen is one of the regions of the body that is most susceptible to aesthetic and functional deformity as a result of genetic characteristics or because of acquired problems associated with obesity, weight loss, pregnancy, or other causes. Abdominal deformity may present as cutaneous flaccidity, localized fat accumulation, or diastasis of the abdominal rectus muscle. Such deformity has long had a negative psychological and physiologic impact on patients who seek a more aesthetic abdominal appearance. Lipoabdominoplasty has proved an excellent procedure for solving this problem and providing patients with the cosmetic contouring they desire.

Lipoabdominoplasty combines two traditional techniques—liposuction and abdominoplasty. This new, conservative concept is based on preservation of the abdominal perforating vessels (subcutaneous pedicle), which are branches of the deep epigastric vessels. As stated previously, this preserves about 80% of the blood supply of abdominal flap compared with traditional abdominoplasty. The nerves and lymph nodes are also preserved, maintaining the flap's cutaneous sensibility to superficial pain and superficial touch by temperature, vibration, and pressure—also an improvement on traditional abdominoplasty.

Evolution of Technique

Traditional plastic surgery of the abdomen results in a high rate of morbidity, because the perforating vessels must be sectioned during undermining of the large flaps. As demonstrated by Munhoz in a postoperative Doppler ultrasound study, these perforators represent 80% of the blood supply of the abdominal wall. Consequently, the vascularity of the remaining flap is supplied only by the intercostal, subcostal and lumbar perforating branches situated in the back and flank regions. Multiple in-

investigators have noted the incidence of ischemia, with tissue necrosis and suture dehiscence, associated with abdominoplasty with liposuction, so surgeons have been reluctant to perform this procedure.

Techniques for undermining the abdominal wall evolved from 1899 to 1957, when Vernon published a standardized technique for extensive undermining of the abdominal wall to facilitate umbilical transplantation.

In previous decades surgeons developed innovative techniques to reduce the surgical morbidity associated with abdominoplasty, obtain a faster recovery, provide a more aesthetic body contour, and produce lower rates of abdominal wall necrosis. The introduction of liposuction by Illouz in 1980 led to the development of techniques that reduced the need for abdominal undermining.

The mini-lipoabdominoplasty described by Hakme in 1985 involved liposuction of the entire abdomen and flanks, with an elliptical resection of the suprapubic skin, plication of the supraumbilical and infraumbilical rectus muscles, without relocating the umbilicus. The complications associated with combined liposuction and abdominoplasty methods are vascular related and were presented by Matarasso in 1991 and 1995. He considered the back and flanks safe areas for liposuction. He did not regard the lateral region of the abdomen as safe, and he cautioned that no liposuction should be done in the central region of the abdomen.

In the 1990s Illouz decreased the extent of undermining and the rate of complications (seroma, hematoma, and most of all, necrosis), reaching zero undermining in 1992 with an article on “abdominoplasty mesh undermining.” The trend toward “abdominolipoplasty,” with or without a small amount of undermining, continued until 1999, when Shestak and Avelar presented the partial abdominolipoplasty method, with no undermining. In 1995 Lockwood reported using Scarpa’s fascia to decrease the tension of the skin closure.

Superficial liposuction, introduced by de Souza Pinto in 1996, became the first fundamental principle of lipoabdominoplasty, because this technique allows more mobility of the abdominal flap so that it can slide down easily and reach the suprapubic region. The second principle is the preservation of abdominal perforator vessels (see p. 3035).

Lipoabdominoplasty was developed by Saldanha and published for the first time in 2001 as a safe option to correct both functional and aesthetic abdominal deformity while achieving better aesthetic results with technical simplicity for surgeons. Saldanha outlined a standardized method for selective undermining between the internal borders of the rectus abdominis muscles.

Indications and Contraindications

Lipoabdominoplasty can be used for any patient with flaccid abdominal skin, adiposity, and diastasis of the rectus muscles. It can be used in smokers and in overweight and postbariatric patients.

Pertinent Anatomy

The abdominal wall skin comprises two elements: the epidermis and the dermis. Beyond the dermis is the subcutaneous cellular tissue, which is made up of two layers of fat separated by the superficial fascia. The deeper fat layer is intimately related to the muscles of the anterior abdominal wall through which the vascular, lymphatic and nervous systems penetrate.

The abdominal muscles are the rectus abdominis, external oblique, internal oblique, transverse, and pyramidal.

Lipoabdominoplasty is based on the vascular anatomy of the abdominal wall, especially of the perforating vessels of the rectus abdominis muscles. The main arteries of each part of the abdominal wall are two superior arteries, the superior epigastric artery and the musculophrenic artery (branches of the internal thoracic artery); and two inferior arteries, the inferior epigastric artery and the deep circumflex artery of the ilium (branches of the external iliac). Branches of the lumbar and intercostal arteries also help to supply the abdominal wall. The veins follow the arteries' paths and nomenclature.

Lymphatic drainage flows caudally to the umbilicus toward the superficial inguinal nodes and cranially to the axillary nodes. Innervation is by the thoracoabdominal, iliohypogastric, and ilioinguinal nerves.

Scarpa's fascia and part of the deep fat layer are preserved to achieve a complete reconstruction of the abdominal wall in the entire lower abdomen—between the umbilicus scar and pubis. Reconstruction is completed when the superior flap is brought down to the pubis.

The upper abdomen is undermined exactly between the internal borders of the rectus muscles that correspond to the area of diastasis, preserving the perforating arteries, veins, lymphatics, and nerves. Munhoz's postoperative Doppler ultrasound study demonstrated that 81.21% of the perforating vessels mapped in the preoperative period were preserved. This validates the hypothesis that this technique results in a lower percentage of complications from flap ischemia.

De Frene et al showed that it is possible to raise perforator flaps after liposuction of the donor sites; they performed breast reconstruction using perforator flaps in patients who had previously undergone abdomen liposuction.

The skin and rectus abdominis muscle are innervated by the anterior branches of the sixth to the twelfth intercostal nerves, which run along the abdominal perforating vessels. Many studies have shown that the loss of sensitivity is significant after classic abdominoplasty.

Preoperative Assessment

The surgeon evaluates the amount of excess abdominal skin and its flaccidity, noting the presence of any striae and their extent.

The thickness and volume of subcutaneous fat are estimated.

The rectus abdominis muscles are evaluated for diastasis.

The surgeon palpates for ventral, lumbar, or femoral hernias. Abdominal wall ultrasound is essential.

The presence of any scarring is recorded, as is a history of previous endoscopic procedures because of the risk of weakness in the abdominal aponeurosis.

A history of previous liposuction should raise a warning flag because of the likelihood of decreased flap mobility.

The surgeon should begin with a high suprapubic incision if there is any question whether a mini-lipoabdominoplasty or full lipoabdominoplasty is indicated.

Preoperative Planning

Marking

The abdomen is marked with the “bicycle handlebar” shape described by Baroudi and Ferreira. The horizontal suprapubic line is 12 to 14 cm long and 6 to 7 cm from the vulvar furcula.

Two oblique lines 6 to 8 cm long are drawn in the direction of the iliac crest to complete the incisional line. The areas that will be liposuctioned and from which the abdominal flap will be raised are marked. When appropriate, the dorsal region is also marked for liposuction.

For better orientation at the beginning of tunnel undermining, the rectus abdominis muscle diastasis is marked (shown here in another patient).

Surgical Steps in Lipoabdominoplasty

- | | |
|-------------------------------------|---|
| 1. Marking | 7. Removal of the infraumbilical strip |
| 2. Infiltration | 8. Plication of the rectus muscle |
| 3. Liposuction of the upper abdomen | 9. Omphaloplasty: star-shaped technique |
| 4. Liposuction of the lower abdomen | 10. Suturing of the layers |
| 5. Preservation of Scarpa's fascia | 11. Placement of drains |
| 6. Selective undermining | 12. Dressings |

Operative Technique

Infiltration

We use the tumescent technique, infiltrating the abdominal region with 1 to 1.5 L of saline solution with 1:500,000 of epinephrine.

84-1
Lipoabdominoplasty
with selective
undermining

Upper Abdomen Liposuction

So that liposuction can be performed safely, the patient is placed in a hyperextended position on the operating table. Liposuction begins on the supraumbilical region with a 3 or 4 mm cannula; the fat of the deep and superficial layers is removed, extending to the flank and reaching the submammary fold. The thickness of the fat is maintained at about 2.5 cm to avoid vascular impairment and contour deformities as in traditional liposuction.

Lower Abdomen Liposuction

Scarpa's fascia is an important anatomic structure of the abdomen and should be preserved in the lipoabdominoplasty. So that the fascia can be seen and preserved, all of the superficial fat layer and part of the deep layer in the lower abdomen should be aspirated with a 6 mm cannula. After the surgeon evaluates the flap descent, the

umbilicus is isolated and the infraumbilical skin resected as in traditional abdominoplasty. If necessary, complementary open liposuction can be performed to remove fat above and below the Scarpa's fascia and create a homogeneous surface to accommodate the superior flap, which becomes thinner in its descent.

Preservation of Scarpa's Fascia

Preservation of Scarpa's fascia is important for a number of reasons: to reduce bleeding because the inferior perforating vessels are spared; to provide homogeneous support for the upper flap, which becomes thinner in its descent; it causes the contention of scars laterally offering better adherence between the flap and the deep layers.

Selective Undermining

The preservation of the abdominal perforating vessels and nerves during the procedure is the second principle of lipoabdominoplasty.

Selective undermining is performed in the median line of the upper abdomen between the internal edges of the rectus abdominis muscles. Undermining laterally beyond this area may damage the perforating vessels, increasing the potential for morbidity and abdominal flap necrosis.

Tunnel undermining may reach the xyphoid process, depending on the need for rectus muscle plication. The tunnel width may vary with the extent of diastasis, because the perforating vessels follow the muscle's separation. The wider the diastasis, the wider the tunnel. The perforating vessels are not damaged if undermining does not extend laterally beyond the internal edges of the rectus abdominis muscles.

The Saldanha retractor can be used to enlarge the surgical site, thus improving visualization of the anatomic structures, which facilitates muscle plication and helps to prevent trauma to the edge of the flap.

The dislocation caused by the liposuction cannula facilitates descent of the flap. Release of the trabecular ligament (as described by de Souza Pinto) in the upper abdomen should be performed to extend the transposition of the abdominal flap to the pubic region, preventing excessive tension on the suture.

Removal of the Infraumbilical Strip

In the median infraumbilical line, a vertical strip that contains Scarpa's fascia and adipose tissue should be removed to expose the internal edges of the rectus abdominis muscles and to facilitate plication from the xyphoid process to the pubis.

Resection of Excess Skin

All excess skin of the lower abdomen should be removed after making certain that the flap easily transposes to the pubic symphysis.

Omphaloplasty

The star-shaped omphaloplasty design is marked on the abdominal wall and a lozenge shape is created on the umbilical pedicle. The cardinal points of the umbilical pedicle are sutured to the cardinal points of the cruciform incision of the abdominal wall. The scar results in a continuous Z-plasty that offers little possibility of retraction.

Suture of the Layers

The surgical site is sutured in two layers, with 3-0 Monocryl on the deep layer and 4-0 Monocryl on the subdermis. The skin is sutured with 5-0 mononylon separate stitches. At this point, the scar can be lowered by resecting a cutaneous strip (1 to 2 cm) without risk of harming the flap or causing too much tension on the sutures.

A continuous-aspiration drain is placed for 1 or 2 days.

Dressing

The wound is covered with Micropore surgical tape, and the dressing is placed while the patient is still on the operating table.

Postoperative Care

The aspiration drain is removed 1 or 2 days after surgery. The dressing is changed on the third and eighth postoperative days when the horizontal sutures are removed. The sutures on the umbilicus are removed on the twelfth postoperative day. A medium compression belt is used until the twentieth postoperative day.

The recovery time for patients who undergo lipoabdominoplasty is midway between that of abdominoplasty and liposuction because it is less invasive, causes little vascular and nerve injury, and presents a discrete dead space. Preserving Scarpa's fascia decreases the dead space, reducing the possibility of seroma formation. These factors result in lower morbidity and enable the patient to return quickly to social and professional activities.

Problems and Complications

DVT, Deep venous thrombosis; PE, pulmonary embolism.

If the surgical steps described are followed systematically, the potential for complications is reduced. The graph above provides data on our 9-year experience with lipoabdominoplasty with selective undermining, comparing the complication rate with that of the traditional abdominoplasties performed. The reduced incidence of seroma, epitheliolysis, dehiscence, and necrosis is statistically significant. Although the reduced incidence of hematoma and deep venous thrombosis/pulmonary embolism remained the same, we cannot consider them statistically because of the small number of cases in which these complications occurred.

The percentage of surgical revisions decreased from 20% to 10% when we began to perform lipoabdominoplasty-only procedures, remaining so for 8 years. The table shows the percentage of surgical revisions required in this lipoabdominoplasty series. The cases of surgical revision required because of complementary liposuction and postoperative skin flaccidity (3.2%) correspond to patients who had undergone previous bariatric surgery and had a great amount of flaccidity. There was a need for scar revision in 6%, which represents 63% of surgical revisions.

Surgical Revision in Lipoabdominoplasty

Pitfalls

Initially, the surgery requires more than 30 minutes.

The procedure should not be performed on patients with a large hernia or even-tration.

A short learning curve is required to assimilate the new procedure.

Outcomes

The learning curve for this technique is short, because the plastic surgeon performs both liposuction and abdominoplasty. As the surgeon gains familiarity with this technique, he or she can produce a harmonious body contour with a shorter postoperative recovery time. A safe liposuction technique in abdominal and costal areas leads to excellent results in almost all cases. In lipoabdominoplasty, preserving Scarpa's fascia reduces the length of the suprapubic scar, compared with the initial marking, in 30% of the cases. This occurs because Scarpa's fascia has a direct relationship with the skin. This can be observed when it is reapproximated, after the removal of the vertical infraumbilical strip. Complication rates are decreased, the aesthetic results are satisfactory, there is less postoperative morbidity, and the need for late surgical revision is reduced.

Results

The combination of liposuction and abdominoplasty at the same surgical setting improves the results, providing greater reduction in abdominal volume and better body contour. In addition, patients' satisfaction with their abdominal rejuvenation results in a decreased need for surgical revisions—and an increased demand for such procedures as they share news of their experience with others.

The table compares the incidence of complications in traditional abdominoplasty to that of lipoabdominoplasty in the 1015 patients in our series who underwent abdominal surgery and were followed by the senior author (O.R.S.) from 1979 to 2008.

Total Abdominal Surgeries, 1979-2008

	1979- 1999	2000	2001	2002	2003	2004	2005	2006	2007	2008	TOTAL
Traditional abdominoplasty	469	25	—	—	—	—	—	—	1	—	495
Lipoabdominoplasty	—	15	45	55	64	62	65	68	71	75	520
TOTAL											1015

From 1979 to 2000 the senior author performed 494 traditional abdominoplasties. In 2007 one traditional abdominoplasty was performed in a case of skin excess in a postbariatric patient, bringing the total to 495 traditional abdominoplasties. In 2000 the senior author began to develop lipoabdominoplasty, performing 520 procedures through 2008. In the first 9 years of implementing this technique, there was a 100% increase in abdominal surgeries by the senior author (before 2000, the average was 35 patients per year; from 2004 to 2008, the average was 75 patients per year). There was a 50% reduction in the need for surgical revisions during the same period.

We observed a decrease in final scar extension when compared with the initial marking in 30% of patients. The initial line always measured 28 cm in length: 12 cm horizontal and 8 cm oblique on each side. In the 520 patients, 156 had a final scar of 25 to 27 cm, with an average reduction of 2 cm from the initial marking. This is a result of the traction of Scarpa's fascia on the skin.

The graceful shape of the umbilical scar has been deemed good to excellent by the team and the patients.

This 42-year-old patient, who had two children, was slightly overweight, with redundant abdominal skin, an abdominal bulge, and stretch marks. She is shown 6 months postoperatively with a lower abdominal scar and a much better contour as a result of liposuction.

This 39-year-old woman, who had one child, had flaccid skin and moderate lipodystrophy, which made her appear older. The rejuvenating effect of lipoabdominoplasty, seen 12 months postoperatively, has provided a contour more appropriate to her age.

This 30-year-old patient had one child. Despite her relative youth, she had a very disharmonious abdominal shape. She is seen 10 months postoperatively; lipoabdominoplasty has produced a more harmonious contour with a natural-looking profile and umbilical scar.

Similar to the previous patient, this 28-year-old woman, with one child, presented with an unattractive abdominal contour. Six months postoperatively, the improved contour is evident. The lower scar accommodated the patient's desire to wear bikinis.

This 50-year-old woman, who had two children, desired a more harmonious body contour. She had redundant abdominal skin and a horizontal umbilical shape that bothered her. Her postoperative photos, 10 months after the procedure, reveal a much-improved shape with a uniform profile that pleases the patient.

This 29-year-old patient, after having two children, requested a better abdominal contour. She had abdominal lipodystrophy, stretch marks, a significant diastasis, protrusion, and a noticeable umbilical diversion. Three months postoperatively, the excellent rejuvenative effects of the procedure are already evident, including a new, higher, centered position of the navel.

Concluding Thoughts

The initial objective of lipoabdominoplasty was to reduce the complication rates in abdominoplasty patients. As the technique evolved, other advantages became apparent. Aesthetic results were improved, because reduced abdominal measures provided better abdominal contour. Recovery of suprapubic sensitivity was faster, because the nerves were preserved. This technique represents an important advance in plastic surgery, improving patient safety. The adoption of lipoabdominoplasty is easy for surgeons who are accustomed to performing both liposuction and abdominoplasty. Patient satisfaction increases, and the need for surgical revisions decreases, leading to a greater demand for the technique.

Clinical Caveats

With lipoabdominoplasty, a better body contour is achieved because liposuction decreases the abdominal measurement.

Morbidity is decreased because the perforating vessels are preserved and there is no dead space.

The incidence of complications is lower with this procedure.

Lipoabdominoplasty is easy to perform because surgeons are already accustomed to liposuction and classic abdominoplasty.

The abdomen is rejuvenated with a more natural profile.

Suprapubic sensitivity is preserved.

Postoperative recovery is faster, and the scar is shorter.

Vibroliposuction or ultrasound liposuction can be used.

The procedure is safe for smokers, obese patients, and postbariatric patients or those who have undergone reversal abdominoplasty.

Surgeons should perform their first lipoabdominoplasties in patients with excess skin flaccidity and extensive fat volume.

Ultrasonography of the abdominal wall should always be performed to identify any asymptomatic hernias and to prevent abdominal perforation by the cannula.

This technique should not be performed in patients with large hernias and eventrations, because bleeding can increase liposuction time. Patients who have had previous laparoscopic procedures also have this risk.

Extra care must be taken in patients who have had previous liposuction and in patients with abdominal scars that suggest previous surgeries.

A high suprapubic incision is recommended if there is any question whether a mini-lipoabdominoplasty or full lipoabdominoplasty is indicated.

CHAPTER 85

Gluteal Augmentation

CONSTANTINO G. MENDIETA

The ability to augment the buttock has existed since 1969, when Bartels et al first described the reconstruction of a unilateral gluteal agenesis by placing a Cronin breast silicone implant above the gluteus muscle. Over subsequent years, other authors described similar reconstructive procedures for the treatment of asymmetry and gluteal depressions. However, it was not until 1973 that the first successful augmentation for cosmetic purposes was published by Cocke and Ricketson from Nashville, Tennessee.

Despite its U.S. origins, gluteal augmentation did not develop a following in the United States, and it was the Latin-American plastic surgeons who popularized and refined the technique as a cosmetic procedure. In 1981 González-Ulloa developed an interest in gluteal augmentation and placed gluteal implants above the muscle through bilateral infragluteal crease incisions (at the bottom of the buttock). He was among the first to develop an implant line that was specifically designed for the buttock, marking the birth of the almond-shaped gluteal implant. Until then, breast implants had been used for buttock augmentation. González-Ulloa published his 10-year experience in 1991 describing his technique as well as a new incision approach, the bilateral intergluteal incision (moving the incision from the bottom of the buttock to the inside of the midline gluteal crease).

Until that time, only subcutaneous buttock augmentation had been described, but in 1984 Robles et al of Argentina published a landmark article in which they described the intramuscular technique through a central single intergluteal incision. Robles also introduced his own line of round gluteal implants, making the choices for gluteal implants more intriguing.

Unfortunately, gluteal augmentation as a procedure lay dormant for the next 10 years, with very few advancements or publications until 1994, when Vergara published his experience with an anatomic implant that he developed for the intramuscular plane. Then in 2000 de la Peña published his work describing a new surgical plane and described the new implant he designed specifically for the subfascial plane.

Gluteal augmentation was now developing apace: we had different incision locations, different implants to choose from, and different planes of placement. However, despite its 30-year history, the procedure remained in its infancy and had not flourished as other procedures had, such as breast augmentation, face lifts, and body contouring, about which many articles had been written. Physicians' interest remained low, since they remained unfamiliar with the anatomy, they perceived a high complication rate, and there were few articles in the literature.

This all began to change in the early 2000s as public interest began to peak with the appearance of Jennifer Lopez, Serena Williams, and other personalities who accentuated and flaunted their curves. As patients began to inquire what could be done to give them more-curvaceous buttocks, physicians' interest began to increase—yet the vast majority remained hesitant because the operative techniques were not well un-

derstood. Patient selection remained a mystery, and no evaluation system existed to universalize the approach. Consequently, surgeons continued to avoid performing procedures on this area of the anatomy.

In 2003 I published my experience with intramuscular implants in which patients described a tremendously high satisfaction rate, but clinically there was a 30% wound dehiscence rate. Up to this point, no article had addressed complications, complication rates, patient selection, implant selection, plane selection, and so on. My focus turned from simply trying to master the technique to trying to decrease the complication rates and make the procedure safer and more appealing to surgeons.

The procedure has evolved significantly over the past 8 years. In this chapter I will focus on how to augment the buttocks safely with implants or with fat. It includes guidelines for patient selection, implant selection, incision location, and surgical plane selection. In addition, information is provided on identifying patients who are at a greater risk for developing complications. Mastery of this procedure requires both knowledge of relevant clinical anatomy and familiarity with the properties of the various implants available to the surgeon.

Patient Profiles: Who Is a Candidate for Gluteal Augmentation?

Gluteal augmentation is not just about making the buttock bigger, but rather accentuating, contouring, and reshaping. The focus becomes volume redistribution, shifting volume from an unattractive zone to a more desirable curvaceous position.

Preoperative and 5-month postoperative views after 1100 cc of fat grafting to the buttocks

With this perspective, even a full-figured woman becomes a candidate, because on closer examination, the large buttock has poorly distributed fat with deficient volume in pertinent aesthetic zones. Liposuction was also performed on this patient's back, waist, and abdomen.

The question is no longer who is a candidate for buttock surgery, but rather what augmentation procedure is best for a particular patient. Liposuction is used for reshaping, and fat grafting is used for fat redistribution, but which augmentation method should be selected becomes our first challenge.

Pertinent Anatomy

A thorough grounding in anatomy and aesthetics is essential for body contouring. We can all recognize a pretty buttock, but translating this aesthetic into surgical results becomes a challenge. Millard emphasized in his principles that to be successful in our surgical design, approach, and ultimate results, we must first understand the beautiful and ideal normal. This is particularly true when dealing with a massive-weight-loss patient, where normal anatomy and proportions may have become grossly distorted.

The gluteus maximus muscle originates primarily along the lateral margin of the sacrum and, to a lesser extent, from the coccyx and sacrotuberous ligament. It continues in an upward curvilinear direction to the posterior iliac spine (identified as bilateral dimples in the parasacral zone). Traditional teachings tell us that the muscle attaches all along the crest, but in reality it only follows the crest for a quarter to a third of its distance—up to the posterior superior iliac spine. From this point it follows a ridge inferior to the crest. The distance from this ridge attachment to the palpable superior crest is variable among patients. The gluteus maximus inserts into the iliotibial tract, and, to a lesser degree, the greater trochanter. The gluteus medius originates along a ridge in the posterior superior iliac crest and attaches in a manner similar to the gluteus maximus.

The superior aspect of the origin of the gluteus maximus plays an important role in defining the ideal buttock. However, buttock aesthetics are not solely dependent on the gluteal muscles. The overall shape of the buttocks is also influenced by bony pelvic anatomy, fat distribution, and, to a lesser degree, skin, if there is laxity or overhang, as is the case in massive-weight-loss patients. Without a doubt, the most significant contributor to shape is fat. Excess fat in the sacrum, upper buttock, flank, and outer legs will distort shape and contour.

The Ideal Buttock

To evaluate the buttock, it is helpful to divide it into quadrants by drawing an imaginary line down the center of the buttock. The ideal buttock has equal volumes on either side of this line and has the shape of a football, but with a slightly wider base.

To assess volume distribution, a horizontal midbuttock line is added to divide the buttocks into four quadrants. The ideal buttock also has equal volumes above and below this horizontal line. In determining the best procedure for a particular patient, the surgeon evaluates all four quadrants as either sufficient or deficient.

There are three other zones surrounding the buttock that are important in this evaluation: the upper inner gluteal–sacral junction, the lower inner gluteal fold–leg junction, and the midlateral gluteal–hip junction.

Upper Inner Gluteal–Sacral Junction: Ideal Presacral Space Shape

The inner gluteal–sacral space should be well defined so that a V shape is apparent; this lower presacral space is appropriately called the *V zone*. As the V zone becomes more visible, the buttock has greater aesthetic appeal.

Solid line marks end of intergluteal crease line; dashed line marks end of upper muscle edge; notice V zone with visible muscle fullness

In the ideal buttock, the edge of the gluteal muscles should be well defined and have a semicircular upward turn. The superior edge should culminate a quarter to a third above the intergluteal crease line.

If this space is not well defined because of lack of muscle volume and excess fat in the V zone, the buttock becomes blunt and appears flat, especially on lateral view.

Lower Inner Gluteal Fold–Leg Junction

To describe this relationship, the intergluteal crease will be referred to as the *midline*. The upper aspect of the crease is easily identified; however, the inferior aspect is defined at the point where the buttock begins to separate from this midline.

In the images above, the red lines indicate how the fullness increases at the lower inner gluteal fold. Notice how the diamond-shaped zone turns from a 45-degree angle into a straight line.

In the ideal buttock, this point of separation from the midline occurs at about the bottom two thirds to three fourths of the muscle. The separation widens until it meets the inner leg junction. At this point the lower gluteal fold has a 45-degree takeoff from the center intergluteal crease line and the inner gluteal fold–leg junction should create a diamond-shaped space. This is a key point in gluteal aesthetics. As the lower inner gluteal fold and inner leg become fuller, the 45-degree sloping line is changed to a more horizontal position, which causes the diamond-shaped space to turn into a straight line, losing its aesthetic appeal. As the fullness increases, it develops an inverse relationship, creating an upward slope (negative angle). Thus the slant of the inner gluteal fold has three possible orientations: a downward 45-degree slope with the inferior gluteal fold ending at the midbuttock or slightly beyond (as seen in the ideal buttock), a horizontal line, or an upward inverse slope.

Improvement of this zone will depend on the severity of the fullness.

Lateral Midbuttock–Hip Contour

In the aesthetic buttock, the lateral midbuttock has no depression. In actuality, this zone may exhibit varying degrees of depression, ranging from no depression to mild and moderate degrees of depression to severe depression.

With volume well established and these three zones evaluated, the next questions become: Is there an ideal gluteal crease length? How important is this to gluteal aesthetics? And what relationship does this have to the gluteus muscle or any of the surrounding areas?

Ideal Interogluteal Crease Length

The interogluteal crease length is usually half the length of the gluteal muscle, but it is centered on the gluteus so that a quarter to a third of the gluteal volume is above the highest crease point and a quarter to a third below the termination point—the takeoff point where the lower inner gluteal fold deviates from the interogluteal crease line.

Ideal Presacral to Intergluteal Crease Length Relationship

The presacral space extends from the midline dimple of the lower back (L5/sacral junction) to the superior aspect of the intergluteal crease. It plays an important role in gluteal aesthetics.

The length of the entire presacral space (*green line*) should be shorter than the intergluteal crease length (*red line*). Ideally, the presacral space should be a half to a quarter the length of the intergluteal crease.

If the presacral space is twice as long as the intergluteal crease length (2:1) (*left*), the crease appears extremely short, giving the illusion of a truncated, flat, underdeveloped buttock. If the presacral space length is less than a quarter of the intergluteal crease length and there is excess fullness in the lower inner gluteal zone, this gives the crease an excessively long, alien appearance (*center*). However, even with this relationship, if the buttocks have adequate volume, especially in the lower third, the overall appearance may be adequate (*right*).

Lateral View Aesthetics

On lateral view, the presacral area should have a nice sweeping curve that has a lazy-S shape (from the back to the bottom of the gluteus). Most of the gluteal volume is central and has equal distribution in the upper and lower gluteal zones, providing a nice C-shaped curve. It has been suggested that the peak of the central mound should be at the level of the pubic bone.

Determining where most of the volume lies (upper, central, or lower buttock) is important in selecting the best procedure for buttock augmentation.

Summary of Key Anatomic and Aesthetic Concepts

One can now easily see that the upper aesthetic unit of the gluteus follows its origin, beginning at the midsacral line, continuing as a semicircular line that connects to the posterior iliac spine (identified as bilateral divots in the parasacral zone), and peaking at 2 to 3 cm above this point. The ideal crease is centered on the gluteus muscle and is half the length of the muscle. The length of the presacral space should be shorter than the intergluteal crease length. In a well-developed buttock with very little lower presacral fat, a visible V zone is apparent that further accentuates the upper inner muscle anatomy; the muscle has a football shape, with equal volumes in all four quadrants. The gluteal unit is marked superiorly by its attachment to the iliac ridge (easily palpated) and inferiorly by the inferior gluteal crease. If incisions are created that fall below the superior insertion point or mark, the shape is distorted. Without a doubt, the most important contributor to gluteal aesthetics is the volume of distribution in all four quadrants. When this volume is adequate, all other aesthetic points can be overlooked and still produce an attractive buttock.

The other key contributor to gluteal aesthetics is the inner gluteal–leg junction. Inferior gluteal aesthetics is defined by a diamond shape at the intergluteal/leg junction. The medial buttock cheeks have a 45-degree takeoff from the intergluteal line and flow into the inferior gluteal crease, which terminates at or just beyond the mid-buttock line. On lateral view there is an S-sweep curve from the lower back as it flows into the buttock, and most of the gluteal volume is located in the central zone.

Clinical Decision-Making: Implants Versus Fat

As I noted earlier, my initial implant complication rates for buttock augmentation were published in 2003 in which I had identified a wound dehiscence rate of 30%, with an implant exposure and infection rate of 2% to 3%. However, in this series, by far the most frequent patient complaint was that the augmentation was “not big enough” (see below), and patients demanded larger volumes.

This patient is shown preoperatively and 2 years after intramuscular medium round implants were placed. The implant augmentation shows minimal difference.

In trying to fulfill patients' expectations, larger implants were used; however, complication rates soared, with wound dehiscence rates increasing to 40% to 50% and implant exposure rates rising as high as 30%. This was unacceptable, making it very clear that not everyone was a candidate for implant gluteal augmentation. But then, who was?

Through a new retrospective review of 150 intramuscular cases, we noted these factors: most of the dehiscence and implant exposures occurred in large patients or patients seeking large augmentations. While at face value this observation seems obvious, it must be remembered that no guidelines or parameters existed for gluteal augmentation. Therefore the question became more complex: What patient is too large? What implant is too big? What is the threshold? To help answer these questions, we evaluated patients based on body frame size and the degree of muscle tension at closure.

To assess body size, patients were divided into four groups: those with small, medium, large, and extra-large frames. Muscle tension was categorized as either having tension or no tension at closure. Implant exposure and wound dehiscence were compared. The results are shown in the table.

Wound Dehiscence and Implant Exposure by Body Frame in 150 Patients

Body Frame	Wound Dehiscence (%)	Implant Exposure Based on Muscle Tension at Closure (%)	
		No Tension	Tension
Small frame 	12*	1-2	12
Medium frame 	30†	3-4	12
Large frame 	40	10	30
Extra-large frame 	80	30	60

*Single midline intergluteal incision.

†Two separate parallel intergluteal incisions 2 cm apart.

Analysis of Implant and Fat Options

Before 2003, when patients presented for gluteal augmentation, implants were my preferred method; 90% of the augmentations were performed with implants and only 10% with fat injections. My preferred method of augmentation today is autologous fat grafting, because this method completely eliminates all the implant-related complications (wound dehiscence, implant exposure, capsular contracture, seroma, implant rotation, extrusion, and so on). Implants are used only in patients who do not have enough fat for a significant clinical augmentation (small-framed individuals) or borderline patients who cannot gain 4.5 to 9 kg (10 to 20 pounds) (some small- and medium-framed individuals). The complication rates in these patients, when using a double parallel intergluteal incision with a no tension on muscle closure, was only 2% to 3%. However, this means that the exact implant size to be used can only be determined intraoperatively with the use of sizers. If the patient desires a larger augmentation, we can perform simultaneous fat grafting to help enhance volume and shape, but the implant size depends on the patient's anatomy, meaning the degree of muscle and skin laxity.

Large- and extra-large-framed individuals are ideal for fat transfers, given that excess fat and implant complications are far too high in this group. The challenge therefore lies in medium-framed individuals, because they may or may not have an adequate amount of fat. It is in these patients that the surgeon's estimate of the fat that he or she feels can be extracted plays a crucial role. This estimated amount may vary significantly, depending on the surgeon's experience and comfort level. If the surgeon is in doubt, the patient can be asked to gain weight.

Thus the central question is: Just how much fat is needed to obtain a clinically significant buttock augmentation?

The Amount of Fat Needed for Augmentation

Every patient's desires and goals are different, and often the patient's anatomy may limit the amount of augmentation, depending on the laxity of the muscle and skin, but as a general rule gluteal augmentation with fat requires 400 to 1100 cc of good transferable fat per side. Obviously, the larger the patient, the larger the required volume; in a small-framed individual, 300 to 450 cc per side will be needed; in a medium-framed person, 450 to 850 cc per side; and in large- and the extra-large-framed patients, 750 to 1100 cc per side. The overall amount that can be placed will be influenced by the degree of muscle and skin laxity as well as the gluteal muscle dimensions.

The true amount of fat that will be available for transfer cannot be determined preoperatively; there are several variables that are only revealed during the surgical procedure. We must remember, not all of the aspirated fat is viable, and each patient has different fat characteristics: some fat is easily destroyed on suctioning, whereas other fat is very fibrous and resilient. Complicating the issue further, some patients have a bloodier aspirate, which can further limit the amount of fat we can extract safely. Other patients have such a strong propensity for leaving cannula track marks on the skin that it limits the aggressiveness of our suctioning, further limiting the amount of available fat. These variables cannot be predicted before surgery, which makes the quantity of transferable fat unpredictable. As a general rule, only half to a third of the total supernatant aspirate is acceptable for transfer, which means that 1000 to 4000 cc of total supernatant fat is needed to produce 600 to 2000 cc of good transferable fat. These volumes have been substantiated by others.

Clearly, some patients will not have that volume to spare. A small-framed individual, as stated before, is best augmented with implants or implants and fat. If in the surgeon's opinion a medium-framed individual does not have enough fat or the estimated volume is borderline, the patient is asked to gain 4.5 to 9 kg (10 to 20 pounds), depending on the surgeon's estimate of how much fat the patient will have available. Often the patient is brought back for a reevaluation after a 4.5 kg (10-pound) weight gain and is reassessed. If the available volume is still in doubt, the patient is asked to gain more weight. If the patients cannot gain the weight and the surgeon is still in doubt as to whether the needed volume will be available, there are three options:

1. The patient's buttocks can be augmented with whatever fat can be harvested, with the patient fully aware that the procedure may fall short of her expectations, and she may require a second procedure if she desires further augmentation. The second procedure can involve either more fat transfers after a second weight gain, or placement of implants.
2. The buttocks may be augmented with implants only, but the size of implant may be limited, depending on her muscle laxity. The goal is to place the largest implant that does not create muscle tension at closure. This cannot be determined until surgery, and this may limit the desired size.
3. Therefore a better option would be to use a combination of implants and fat, the implant size will be determined during surgery, and the fat will be used to further enhance shape and volume.

IMPLANT AUGMENTATION

There are three main issues that must be decided when selecting implants: shape, size, and texture. The implant content can be a solid silicone elastomer, or silicone cohesive gel. The gel implants are used outside the United States, whereas U.S. surgeons are limited to the use of elastomer implants.

Implant Shape Selection

The most common shapes are anatomic, oval, and round; the shape selected will depend greatly on which plane is chosen to augment the buttock, subfascial or intramuscular. Each plane has different tissue dynamics and responds very differently to augmentation.

Augmenting the Subfascial Plane

In this plane, tissues are more pliable, but they are thinner. If implants are improperly selected, they may become palpable with visible edges, and over time gluteal ptosis may develop.

This patient's subfascial round implants were placed too low and descended over time. This is particularly likely to occur if round or oval implants are used.

The best subfascial implant is the one designed by de la Peña; his implant is specifically designed for this plane, and he has spent a significant amount of time designing, engineering, and developing this particular technique. This plane offers a quicker recovery with much less postoperative pain. For surgeons outside the United States who can use silicone-gel implants, palpability is not a big issue. If the patient has good tissue coverage, with proper patient selection and the use of gel implants, a nice natural augmentation can be achieved.

In the subfascial plane, the only decisions that remain are size selection and implant texture. De la Peña developed some excellent preoperative external templates (*above*) that guide the surgeon in size selection. In terms of implant texture, I prefer the smooth implants, because I have noticed a higher delayed seroma rate with the textured implants.

Intramuscular Plane

In the United States we are limited to the elastomer implants, and although they have become softer, these implants are firmer, more palpable, and have less give than gel implants; therefore obtaining tissue coverage is a priority. Placing the elastomer implants in the muscular plane will help camouflage the firmness of the implant, producing a more natural feel and appearance. Given the implant restrictions for U.S. surgeons, this plane becomes more appealing. The intramuscular implant selection process involves deciding on implant shape, size, and texture. Again, the smooth implant is preferred, because there seems to be a lower incidence of seroma formation.

The implant shape for the intramuscular plane requires evaluating two aspects: the muscle height-to-width relationship in the PA view, and the volume of distribution in the lateral view.

Muscle Height-to-Width Ratio

To find the muscle height-to-width ratio, the superior and inferior points of the gluteus muscle are identified, as well as the most medial and lateral points. At a glance, one can see a height-to-width relationship that will fall into one of three ratios: short muscle, 1 to 1; intermediate muscle, 1 to 2 to 1; or tall muscle, 2 to 1. The ideal buttock is intermediate but leans more toward a 2 to 1 relationship.

The gluteus is divided into three zones: upper, central, and lower

The short muscle is best augmented with round implants, because they have similar ratios (1 to 1); the tall muscle (2 to 1) is best augmented with an anatomic implant. The intermediate muscle has the most flexibility, because any of the three types could be used: round, anatomic, or oval. However, in these cases it is best to use the lateral view to make our final decision.

The Lateral View

The lateral view is used to evaluate where most of the bulk of the gluteal volume is located: upper, central (midbuttock), or lower buttock.

If the bulk is in the upper buttock, an anatomic implant will create the best result, because the anatomic shape adds most of its volume inferiorly. If in these cases a round implant is used, it will accentuate the already full upper buttock, which in turn will accentuate the lower gluteal deficiency, making the buttock look very disproportionate. If the bulk is central, the buttock is already well balanced, so any implant will produce an attractive result; I prefer the oval or round implants. If the bulk of the gluteal volume is in the lower buttock, a round implant will look best, because the round implant adds most of its projection in the upper and central zones, equalizing the volumes throughout the buttock.

This patient with a double-bubble deformity had round implants placed. Preoperatively most of the volume was in the superior quadrant; the implants accentuated the deformity in both cases.

Implant Size Selection

Selecting implant size requires a fine balance of trying to please the patient with her desired size and trying to prevent the complications of implant exposure and wound dehiscence. Often these goals conflict: the tissues will not allow as large an augmentation as the patient desires. In these cases, fat grafting can be combined to further increase volume.

Decreasing Implant Exposure

In attempts to decrease implant exposure, I spoke with my mentor in gluteoplasty, Dr. Jorge Hidalgo, and revisited the operation. Once the implant is in place, the muscle edges should almost be opposing (“kissing” edges); this way, very little tension is placed on the muscle closure. Some patients have a very lax or loose muscle and can easily accommodate large implants, whereas others have very tight, fibrous attachments with dense muscle fibers that can barely tolerate medium-sized implants. Interestingly enough, the degree of athletic build or activity has nothing to do with the degree of muscle tension. I have seen body builders with lax muscles and sedentary patients with very dense, tight fibers. There seems to be a genetic and cultural predisposition with individuals of African descent having the tightest attachments.

Because each patient’s anatomy is unpredictably different and implant exposure rates rise as tension increases, implant size cannot be guaranteed or determined before surgery. Sizers are used intraoperatively to identify the largest implant the body will accommodate without creating excessive muscle tension at closure. If the patient desires a larger augmentation, in 3 to 6 months the surgeon can either place larger implants (the muscle having been stretched), or can perform fat transfers. Fat grafting can also be performed at the same time as the implant augmentation.

Intramuscular Surgical Procedure Technique

Preparation

Preoperatively dexamethasone (Decadron) 10 mg and clindamycin (Cleocin) 600 mg are administered intravenously. Pneumatic compression stockings are placed and functioning before anesthesia is induced. Because the surgical procedure takes only 1½ to 2 hours, placement of a Foley catheter is unnecessary.

Anesthesia and Positioning

The procedure can be performed under general anesthesia, or with spinal or intravenous sedation. The patient is placed in the prone position with a pillow under the

pelvic bones to jackknife the pelvis and aid in muscle visualization and dissection. The elbows are flexed with the arms out to the sides at less than 80 degrees (the beach position), and all pressure points are padded. The pneumatic compression devices are rechecked.

If the procedure is to be done with the patient under general anesthesia, I suggest placing a draw sheet under the patient before induction. Once the airway is secured, with aid of the draw sheet, anesthesia in control of the airway, and staff assisting with arm positioning, the patient is rotated to the prone position. The arms are secured and the pillow placed under the pelvic bones. It is important to ensure that all pressure points are well padded and that the pneumatic compression devices are functioning.

Once satisfied with positioning, the buttocks and back are prepared and draped. The gluteal area is prepared from the knees to the upper back and as far laterally as possible. Draping should leave the entire gluteal zone and lower back exposed; a gauze soaked in povidone-iodine (Betadine) solution is placed over the anus and secured with 2-0 silk to avoid contamination (*left*). A sterile towel is placed over the gauze to cover the anus and the inner gluteal zone (*right*). This towel is secured to the skin with 2-0 silk so that there is no space between the towel and skin. All gloves and gowns are changed.

Markings

Preoperatively the areas to have liposuction or fat transfers are marked with the patient in the standing position. The intraoperative markings are minimal, identifying only the tip of the coccyx and infragluteal crease (this helps to identify the drain exit points). Most of our markings relate to incision placement.

Incision Design/Selection

In 1969 Crocket used a unilateral infragluteal incision for reconstructive purposes. González-Ulloa used a bilateral infragluteal approach for his subcutaneous technique, but given the visibility of these scars, they were never in favor. Robles placed the implants in the submuscular position through a hidden single intergluteal incision. This became the incision of choice because of its inconspicuous nature.

Performing gluteal augmentation with implants has been very humbling, because complication rates have remained high, although we have explored many avenues to decrease wound dehiscence and implant exposure: fibrin glue; platelet gels; quilting sutures; drains; variations of the central intergluteal incision; scalpel dissection versus cautery dissection; immobilization; a variety of postoperative care techniques, including fewer office visits (to decrease wound irritation); changes in antibiotics; a variety of garments, and more. No matter how our preoperative, intraoperative, and postoperative care was manipulated, we saw no improvement. Other investigators published articles, and I saw that they did not share my high wound dehiscence rates or issues. However, it became clear that the single midsacral incision was not the best approach in my series, so I began to use bilateral parasacral incisions, which I later learned had already been described by González-Ulloa. These incisions avoid the sacral midline, with its poor circulation. In my last 12 cases, no dehiscence has occurred.

These incisions are designed as follows: with the patient in the prone position, the tip of the coccyx is palpated and marked; staying exactly in the sacral midline the central intergluteal crease is drawn from the tip of the coccyx 8 cm cephalad. The future incisions are marked 1 cm from this midline so that both incisions are 2 cm apart in the inferior and middle portions. If these lower distances are not respected, central skin necrosis may occur. As the incision reaches the upper buttock, it follows the upper gluteal curvature (this occurs at about the 6 cm mark from the coccyx). This design produces two 8 cm incisions that parallel the midline from the tip of the coccyx and extend cephalad following the upper gluteal curvature.

The incisions at their inferior and middle portions have a 2 cm separation; in their upper portion, a 4 to 5 cm separation. The eventual scars remain hidden in the gluteal cleft. Although the upper incision may be seen in some patients, it is hidden in bikinis.

Skin Flap Dissection

The incision sites are infiltrated with 10 ml of 1% lidocaine with epinephrine 1:100,000. Tumescient fluid is injected into the intramuscular and subcutaneous tissues, as well as the areas to be suctioned. With the surgeon approaching one side at a time while standing on the opposite side of the gluteus to be worked on, the incision is made down to the gluteal fascia. The tissues are placed under upward traction with hooked retractors. The beginning of this dissection is tricky, because the muscle fascia comes up relatively quickly and takes an upward, sloping turn. Care must be exercised to avoid getting into the muscle and losing the plane. With the aid of deeper retractors, the dissection is continued, making certain to preserve the fascia on the muscle (a key point in this approach; if the fascia is not preserved on the muscle, there will not be enough good closing tissue for implant coverage). The dissection can be done with electrocautery or, for a less heated dissection, with a gauze pad wrapped around the thumb, digitally elevating the subcutaneous tissues with an upward, sweeping motion. The goal of the initial subcutaneous dissection will be to expose just enough of the muscle and fascia to allow implant placement (this usually means about 5 to 6 cm of subcutaneous dissection).

Muscle Dissection

Before beginning the dissection, it is important to understand the anatomy. The major muscles in this zone are the gluteus maximus, minimus, medius, and piriformis. The maximus has transversely oriented fibers and is one of the largest muscles in the

body; its superior half covers the medius, which has vertically oriented fibers. The plane between these muscles is more distinct in its superior portion (at the level of the posterior superior iliac crest). Moving caudally, the fibers integrate and become indistinguishable. Because our dissection is performed at the gluteal midlevel, there will not be clear identifiable planes, muscle groups, or layers. It is a blunt intramuscular procedure with components of direct visualization, the goal being to maintain a 2 to 3 cm muscle thickness of coverage for the implant. The gluteus muscle is about 4 to 6 cm thick, so maintaining a 3 cm intramuscular dissection allows the muscle to remain and still provide coverage over the crucial nerves and vessels.

Using the midsacral level as the reference point, the fascia is opened following the direction of the muscle fibers for a length of 5 cm.

The intramuscular dissection is started by using a long hemostat and spreading perpendicular to the muscle for a depth of 1 cm. At this point, the surgeon switches to a ring forceps and continues the perpendicular muscle spread for another 2 cm (a total of 3 cm coverage). During the forceps dissection, one can see glistening fascia fibers that are present at different levels of the dissection. If the 3 cm depth has not been reached, the fascia is incised and dissection continues until the 3 cm mark is reached. The forceps dissection creates only a small muscular opening that must be enlarged. With the use of cautery, the muscle incision is opened medially and laterally to its full fascial incision length. Once this depth is achieved, the Deaver retractors are introduced on both sides of the muscle and spread. Up to this point, the procedure has been relatively bloodless; the dissection now becomes blunt, and some blood loss (about 50 ml) will occur. Remember, this is an intramuscular procedure; there is no real areolar plain, as in breast augmentation. The closed ring forceps is used to bluntly push and create the muscle pocket; the muscle pocket should be kept 3 cm thick throughout. It is best to start the pocket dissection in the superior lateral direction. A key point to this portion of the dissection is to tilt the tip of the ring forceps down to about 45 degrees, because the surgeon's tendency will be to unconsciously tilt the forceps upward and pierce through the muscle. If this happens, one can dissect deeper or convert this part of the implant to a subcutaneous position (it is better to dissect

deeper). The dissection continues in a sweeping counterclockwise motion from a superolateral to superomedial direction by a back-and-forth pushing motion of the ring forceps. At this point, with a pocket somewhat created, under direct visualization and with the aid of retractors, the surgeon further defines the pocket with the Aiache gluteal muscle dissector, a serrated instrument. If this dissector is not available, the surgeon can use an index finger or a curved Van Buren sound to push the fibers. At this point little dissection will be done inferiorly. A lap pad is placed in the wound to clear out any blood.

Expander

To help define the pocket further, the surgeon places a breast implant expander and overinflates it until no further expansion can be obtained. The expander will stretch the muscle and help to indicate areas that require further dissection. It will also help define the inferior dissection. In the past, the inferior dissection was limited to an imaginary line that spanned from the tip of the coccyx to the greater trochanter of the femur; this limitation placed the implant in a very high and unattractive position. As surgeons have gained familiarity with this procedure, the inferior dissection has been refined so that the dissection extends 3 to 5 cm below the coccyx, placing the implant in a more anatomic location with improved aesthetic contour. To ensure safety, the inferior dissection is performed with the aid of the expander in place; blunt finger dissection is used to push muscle fibers away from the implant in an inferior direction. The majority of the inferior dissection is done using finger dissection to maintain the muscle thickness and avoid instrument injury to any structures. On occasion, the surgeon may encounter some very dense and tough fibers that cannot be broken with finger manipulation. In these cases, the expander is removed and under direct vision these fibers are freed using the Aiache or Van Buren dissectors or even cautery.

It should be kept in mind that the sciatic nerve is deeper than this dissection. An important landmark is the acetabulum of the femur, which is easily palpated and sometimes seen. If the acetabulum can be palpated, the nerve lies in a groove that is immediately lateral to this structure and is well protected. Occasionally one may encounter the inferior gluteal or superior gluteal arteries; rarely are these cauterized or ligated. However, if this is necessary, it will not create a problem, because the maximus is a type III muscle with excellent blood supply.

Sizers and Implant Size

Once the surgeon is satisfied with the dissection, a sizer is inserted to determine the appropriate implant to be used. When the implant is in place, the muscle edges should be in close proximity, with very little tension at closure (this is one of the key steps in the procedure). Every patient will exhibit different muscle thickness, tightness, and characteristics; this is not related to an athletic build or body size. It is difficult to

predict whose tissues will be lax or tight. Therefore it is often helpful to have a variety of sizes available in the operating room to help assess the largest implant that this particular patient's muscle will accommodate with minimal tension.

Drains

After the implant size has been determined, a Jackson-Pratt drain is introduced in the pocket and brought out through a separate stab incision in the infragluteal crease. Use of the drain has decreased the incidence of seroma. At this point the pain pump and catheters can be placed; these are brought out through the upper medial buttock.

Implant Placement/Closure

The implant pocket is irrigated with 10 ml of 1% lidocaine with epinephrine 1:100,000 mixed with 5 ml of bupivacaine (Marcaine) 0.5% plain. All gloves are changed, the implant is soaked in antibiotic solution, and the incision is thoroughly scrubbed with a scrub brush using Hibiclens. A new sterile towel is placed over the buttock; the implant is rolled into a cigar shape and introduced. A sterile sleeve may come with the implant; this is used to introduce the implant and help avoid implant contact with the skin—*the surgeon should be prepared to struggle*. Sometimes, if the muscle is tight, it will have to be incised at its insertion along the sacrum for about 0.5 cm to create more space. (The surgeon should try to avoid having to do this, because it does make it more difficult to close). Care is taken to leave a cuff of tissue so that it can be closed over the implant. Any irregularities are corrected with further pocket refinement utilizing a curved dissector. The drains are checked for any kinking to ensure that they are in a good position. The muscle is closed with 2-0 Vicryl. The subcutaneous wound is closed in layers with a final running 3-0 Vicryl. The opposite side is now completed in a similar fashion.

Postoperative Care

Activities

For the first 2 to 3 weeks the patient is instructed not to sit, to sleep on the stomach, and when relaxing (watching TV, visiting with friends, reading the paper), to be in the prone position or standing. The patient may conservatively ambulate around the house but is asked to limit activities to avoid wound friction and trauma. When traveling to the office, the patient is asked to lie prone in the back seat of the car.

Most wound dehiscence occurs about the fourteenth postoperative day; wounds are checked on this day. If the wound is intact, the patient is seen for follow-up a week later. At the third postoperative week, the patient is cleared for sitting and driving and is encouraged to start stretching exercises. If the wound is marginal,

the patient is followed closely but is not allowed to sit or drive for at least 2 more weeks until the wound appears stable, or, if the wound dehiscd, until granulation tissue has developed.

The patient can usually return to work 2 to 3 weeks postoperatively.

Return to the gym will depend on wound status. If all is well, the patient can resume exercise 6 weeks postoperatively. If the wound is compromised, it may be 2 to 3 months before workouts are appropriate.

After 3 months the patient is cleared for all types of activities (bungee jumping, motorcycle riding, or any other vigorous activity). At first, the implants will feel very firm (like sitting on rocks); it will take 3 months for them to “soften up.” After that time, they feel like a well-worked-out buttock.

Garments

If liposuction was performed, the patient wears a body garment for 4 to 6 weeks. If no liposuction was performed or the liposuction was limited to the waistline, an abdominal binder that wraps around the upper buttock and waist line is used for 2 weeks. This binder seems to give patients more comfort and less pain than not having any garment.

After the third week, if all is well, the patient is cleared to start sitting.

Bathroom

Privileges are given, but the patient is encouraged to urinate in the shower while in the standing position.

Since the patient is usually constipated (because of pain medications), bowel movements are not likely to be an issue until a week postoperatively.

Nevertheless, if the patient must defecate, it is permissible to sit, but with assistance. The patient is instructed to use baby wipes and to wipe in the standing position while leaning forward on a countertop, wiping once (repeating with a fresh towelette) from top to bottom until clean.

Postoperative Visits

To avoid excessive ambulation, the patient is seen on the third postoperative day for a wound and drain check. The drains are removed when there is less than 30 ml of drainage per 24 hours, usually about 1 week postoperatively. Oral cephalexin 500 mg three times a day is used until the drains are removed. If the amount of drainage remains high at 1 week after surgery, the surgeon must consider balancing the risk of infection from the prolonged presence of drains against possible seroma formation resulting from early drain removal. If drainage persists, tetracycline is placed through the drain and the tube is clamped for 3 hours. This sclerosing agent helps to decrease output. The patient is seen the following day and the process is repeated if necessary. If drainage persists after 10 days, the drains are removed regardless.

Postoperative follow-up visits are scheduled for the third, seventh, tenth, and fourteenth postoperative weeks. If the wound's condition is questionable, the patient is seen either daily or every other day between postoperative days 14 and 21. If the wound is intact by the third week, the patient is seen 1 month later, then 3 months postoperatively, and finally at 6 months. If the wound has dehisced, the patient is usually seen daily until the wound is stable (with granulation tissue forming), then weekly or every other week.

Problems and Complications

As the technique and procedure have evolved, implant complications have been decreased by attention to the following principles:

- Incisions are placed in the intergluteal fold, but as separate bilateral incisions, each placed 1 cm from the center midline.

- Using sizers, the correct implant size is determined based on muscle tightness. The muscle edges should be almost kissing when the implant is placed, before muscle closure.

Individuals with a large or extra-large frame seem to have a higher implant complication rate, because they usually require larger implants, which can lead to greater tension at closure and a greater potential for complications. In these individuals augmentation is best done with fat or dermal flaps. With these modifications, this procedure has worked well.

Wound Dehiscence

Most dehiscence will occur near the fourteenth postoperative day but can occur as late as 3 weeks postoperatively. In our original series, published in 2003, the rate of dehiscence was 30%. The central single sacral incision had the higher dehiscence once the bilateral intergluteal incisions were performed. One dehiscence occurred in 18 cases. Although the case number is small, the procedure shows tremendous promise.

If the wound does dehisce, it can be locally explored at the bedside to see whether the implant is exposed. If it is not exposed, traditional wound care and management are implemented. Closure may take 1 to 3 months. If the implant is exposed, secondary surgery is required using implant salvage techniques (posterior capsular flaps for coverage).

Implant Exposure

If no tension is placed during muscle closure, the incidence of exposure is low (about 2% to 3%). If an excessively large implant is placed or in patients with extremely tight muscle fibers with very little stretch, the incidence is higher. Patients are informed that implant size cannot be determined preoperatively, because the most significant variable to implant size is the patient's particular muscle tightness, which can only be determined intraoperatively. I attempt to place the largest implant the patient's buttock can accommodate. If a larger size is desired, an implant exchange can be performed 3 to 6 months later, and at this time a fairly large implant can be used, since the muscle has been expanded and stretched. Complication rates in such instances are very low, and recovery is extremely quick, with return to work in 5 to 7 days.

If the implant is exposed and secondary surgery is required, the wound is irrigated and the implant usually is exchanged. If the exposure is large, posterior capsular flaps can be used to aid in implant coverage. Patients are advised that these are implant salvage techniques and may be unsuccessful, requiring implant removal.

Infection

Postoperative infection is rare, with an incidence of 1% to 2%. If an infection does develop, removal of the implant may be required. Infections most commonly occur around the tenth to fourteenth day but have been seen as late as 3 months. However, implants have been salvaged through secondary surgery to exchange implants and the use of a closed antibiotic irrigation system. The pocket is irrigated for several days until the infection resolves. Again, patients are advised that these are salvage techniques and that implant removal may be necessary.

Seroma

The use of drains has decreased the incidence of immediate seroma. Late seroma has an incidence of 3% and is usually seen approximately 6 months postoperatively, although it can occur several years later. Late seroma has mainly been seen with the use of textured implants. Resolution has required surgery with implant exchange (substituting smooth implants), partial capsulectomy, and drainage.

Capsular Contracture

Capsular contracture has a 1% incidence; it is improved with implant exchange and partial capsulectomy. It may recur.

Neurapraxia

No sciatic nerve injuries have occurred in my patients. Patients will complain of sciatic-type discomfort in the first month after surgery because of swelling. In these patients symptoms are improved with stretching exercises and administration of vitamins B₁₂ and B₆, methylprednisolone (Medrol Dosepak), and oral gabapentin (Neurontin) 100 mg given twice daily. After 1 week, if symptoms have not improved, the dose of gabapentin is increased to 200 mg twice daily. Most of these symptoms will improve and disappear over the next 1 to 3 months.

Implant Rotation

Implant rotation is not an issue with round implants; however, there is a small (less than 1%) incidence of implant rotation with anatomic implants. This can be corrected by placing internal capsulorrhaphy sutures.

Chronic Pain

Chronic pain usually does not occur. When it does, possible causes include myositis, fasciitis, capsular contracture, nerve impingement, and scarring. Sometimes the implant may be too large and cause pain when the patient sits, because it forces itself onto the muscle attachment at the posterior iliac crest. In such a case, changing to a smaller implant may help; in a patient with an anatomic implant, changing to a round implant may help.

AUGMENTATION WITH FAT GRAFTING

There are three main components to be considered in fat grafting: fat harvesting, fat preparation, and fat injection. There are many different approaches to harvesting and preparation and physicians regularly debate which one is superior. To date, there is no scientific evidence that one approach is demonstrably better than another for fat survival. Although the debate continues as to the best harvesting method (machine versus syringe aspiration, syringe size, cannula size, and other factors) and the best fat preparation method (straining, centrifuge, decanting), there is little debate on the best injection technique. It has been clearly established that small amounts of fat need to be placed in layers using multiple repeated passes, as opposed to single globular-type injections. This basic layering technique is what makes fat grafting work. This technique has been well demonstrated for small-volume transfers and remains the cornerstone for large-volume transfers as well. However, large-volume augmentations are very different from small-volume augmentations. The primary difference is the recipient site. In large-volume placement, the surgeon is injecting into very large muscle groups with excellent blood supply as opposed to smaller, tighter,

less-vascularized spaces. This is where my technique to harvesting, preparing the fat, and choosing the infiltration syringe and cannula size differs from that of many of my colleagues. The layering principle remains the same.

Technique

The large-volume fat grafting technique is straightforward, cost effective, and time efficient. There is no need for expensive or fancy equipment. The simplicity and speed are related to three factors:

1. Fat harvesting is performed with a larger-bore cannula (4 mm and on occasion 5 mm for the deep layer).
2. The aspirate is separated into its components by the use of a very large metal strainer (600 microns).
3. The pure fat injections are done with large-volume syringes (10 and 60 cc syringes) and 2.4 to 3 mm cannulas.

Nearly all the procedures are performed with the patient under general or intravenous sedation in my office-based AAAASF-approved surgical center (only ASA 1 and 2 patients). The procedure takes 2½ to 3 hours to perform. The surgical team is very small, consisting of me, my surgical assistant, and a circulator; my assistant helps position, turn the patient, and prepare the fat.

Infiltration

The tumescent fluid is infiltrated through the access incisions; the exact locations for these are determined when the patient is on the operating room table. On average, 4 to 5 L of tumescent fluid is used per case.

Tumescent Mixture

The fluid consists of 1 L of prewarmed Ringer's lactate solution mixed with 1 ampule of 1:1000 epinephrine. The amount of lidocaine used will vary, depending on the type of anesthesia being used. If the patient is under general anesthesia, then 20 ml of 1% lidocaine with 1:100,000 epinephrine is used. If the patient is under intravenous sedation, 50 ml of 1% lidocaine with 1:100,000 epinephrine is used; 10 ml of bupivacaine (Marcaine) 0.25% is used as well.

Harvest

Liposuction is performed with the power-assisted machine using a 4 mm cannula with the fat being collected in 1500 ml glass bottles that work much like a large Lukens trap.

One connector tube goes from the handpiece into the glass bottle and another from the glass bottle to the liposuction machine. The liposuction machine is set at a suction power of 22 to 23 mm Hg.

Once the bottle is full, it is emptied into a regular strainer that has been sterilized. The strainer will separate all fluid (lactated Ringer's solution, blood, triglycerides, and emulsified fat) from the intact fat cells.

There is absolutely no fluid in the fat. The fat is then transferred to 60 cc syringes.

The well-established methods of centrifuging and decanting work well for facial fat grafting procedures, but the face requires small volumes that can easily be handled with these methods. For fat transfer in the buttocks, on the other hand, large volumes (4 to 6 L) are used, and while large centrifuge machines exist, they are very bulky, require additional personnel, and add a tremendous amount of time to the procedure. Decanting is not efficient with such volumes. The most efficient method for me has been straining. The straining process is remarkably easy. It requires a large metal strainer (which can be purchased at the local grocery store, Target, Wal-Mart, or kitchen accessory store for approximately \$6 to \$10), a wooden tongue blade to help swirl the aspirate, two or three sterile bowls (one to collect the strained fluid and the others to place the supernatant fat), and one large, nonsterile bowl for the discarded strained liquid. Critics of this open straining technique argue that the process is not closed and therefore exposes the cells to air, potentially increasing fat cell trauma and death. I have not noticed this to be an issue in assessing the results.

Passive straining takes far too much time; the dense fat will frequently clog the fine mesh holes, slowing the process further. To expedite this process, my assistant picks up the strainer and repeatedly shakes it back and forth, much like a chef would strain spaghetti. If this active straining technique is not working well and the fluid refuses to strain, a tongue blade is used to swirl the aspirate and let the fluid flow through. Care is taken not to forcefully scrape the tongue blade on the bottom or sides of the mesh to avoid destruction of fat cells. The swirling must be gentle and at midstrainer level, the idea being to avoid squeezing the fat cells. Once all the fluid is sieved, the supernatant fat is placed in a 1000 cc collecting metal bowl and covered with a sterile towel. The entire process is repeated until all currently available aspirates have been strained.

Once the bowl is full, 10 cc of antibiotic solution (clindamycin 600 mg mixed in 20 ml of saline solution) is added and the fat is swirled again.

If I am still harvesting, my assistant will proceed with syringe loading. Because we are working simultaneously, there is no down time between harvesting and preparing fat. This entire process moves smoothly and quickly, like a well-coordinated two-person orchestra.

The following reference values should be noted:

The amount of tumescent fluid injected is usually 5 L.

The amount of intraoperative fluids required is usually 4 to 5 L.

It takes 5 to 6 L of aspirate (fluid and fat) to obtain 2 to 3 L of supernatant fat.

Syringe loading depends on fat density. My transfers are done using a 10 cc syringe connected to a Tulip Luer-Lok 2.4 by 20 cm cannula (for subcutaneous injections) and a 60 cc Luer-Lok syringe using a 3 by 15 cm Luer-Lok Byron cannula (for intramuscular injections). A cannula thinner than 2.4 mm is too flimsy and may bend during injections.

On rare occasions the fat is extremely fibrous and will not pass through the small syringe Luer-Lok opening. In these cases, the fat is transferred using a large-bore 60 cc Toomey syringe connected to a large-bore 4 mm harvesting Toomey cannula.

It is important to assess the quality of the fat as it is being strained. Occasionally it is difficult to tell whether the fat density will be an issue; in these cases, the Luer-Loks are loaded, and if an issue develops, the Luer-Lok syringe is emptied into the Toomey syringe, and for that syringe only, the Toomey system used. Rarely, the entire aspirate is fibrous in which case the entire injections are done with the Toomey system. I always have these syringe and cannula readily available since I never know when I might need them.

Loading

The 60 cc Luer-Lok syringes are loaded in the following manner: the syringe plunger is temporarily removed while the fat is poured using a small 50 cc metal cup.

All four 60 cc syringes are loaded while the 10 cc syringes are loaded quickly and easily using the transfer tool connected to the 60 cc syringe.

At this point I am still harvesting, so my assistant is on hold until the next batch of fat comes through. He or she will repeat the emptying and straining process, collecting the fat in the 1000 cc bowl and adding antibiotic solution to each new batch until we are done harvesting. If the bowl becomes full, we have a spare bowl waiting. The strained fluid is periodically poured into a large plastic nonsterile 3 or 4 L bowl and the fluid is discarded.

The advantage of this technique is that the total procedure time is about 3 hours, compared with following the small fat-transfer principles (harvesting with a smaller cannula, followed by centrifugation, then injection with 1 or 3 cc syringes), which would take about 6 to 8 hours.

The straining system I use is efficient, cost effective, easy to perform with retention rates equal to those published. My experience is clinically based and not scientific; however, it is my impression that I retain 70% to 80% of the fat injected.

The disadvantage to this technique is that I do lose about 10% of cells that are very tiny and sieve through the strainer. The quality of these very small fat cells is unknown; some hypothesize that those are the best cells (stem cell rich); others think that these are not great cells for transfer. In an effort to salvage some of these smaller cells, I have tried using a smaller strainer with 300-micron sizes but even so, I still do not manage to capture many more cells, because these cells are almost liquid in form.

The other disadvantage to my approach is that one needs to do some searching to obtain the necessary equipment. The glass bottle can be obtained through Wells Johnson (Tucson, AZ); it is the 1500 cc model with a rubber stopper. This glass bottle can be resterilized; its initial cost is about \$350. After about 30 cases a new rubber stopper must be ordered. The bottle is sterilized in a regular autoclave, and the rubber tubing by gas sterilization, to make it last longer. (If autoclaved, the rubber starts to break down and will last for only 10 to 15 cases.) Another option is to gas-sterilize the 1500 to 2000 cc plastic containers, which cost about \$2 or less. Some companies may have these already presterilized. Finally, the strainer can be obtained at any store (Target, Wal-Mart) and costs about \$6 to \$10; it is sterilized regularly.

There are many new disposable collection systems coming to the market that will further simplify and speed the process, but currently some of these systems are flawed because they retain too much fluid with the transferred fat-containing fluid, which will be reabsorbed, falsely elevating the absorption rate. With time these issues will be worked out, but in the meantime the system I am using has worked extremely well.

Postoperative Care

Care for patients after fat transfer is the same as that following circumferential abdominoplasties or buttock lifts. If no abdominal work has been performed, the patient is instructed to sleep on her stomach for 2 weeks. This means watching TV, reading, and relaxing in the prone position. For travel to the office, patients are asked to stay

in the back seat, lying on the stomach. Bathroom privileges are given, but patients are asked to urinate in the shower in the standing position. Bowel movements, although welcomed, usually do not occur for 1 week because of constipation from pain medications. If at 1 week the patient remains constipated, one bottle of magnesium citrate is recommended.

If an abdominal procedure has been performed, postoperative care is the same as that provided for abdominoplasty patients. Patients sleep on the back, not on the stomach. Although it may seem contradictory, it is better to tolerate some fat loss than to have to deal with abdominal skin pressure necrosis. A body garment is worn for 4 to 6 weeks, and the patient is able to return to work in 2 to 3 weeks and to the gym in 4 to 6 weeks. No ultrasonography of the buttock area is performed, because this can destroy fat cells. An antibiotic (such as cephalexin) is used until the drains are removed (when drainage is 30 ml or less in 24 hours). Patients may shower on the third postoperative day. The final results can be evaluated in 6 months.

Problems and Complications

Complications associated with fat transfer are rare.

Gluteal Asymmetry

Gluteal asymmetry is not a complication, but rather a preoperative anatomic fact. No two buttocks are the same; patients must be educated about this reality. One side is always larger and different from the other. This disparity was present preoperatively, and it will be present postoperatively.

Infection

The incidence of infection after gluteal augmentation is approximately 1% to 2%. This is usually seen by the seventh to the fourteenth postoperative day. It will present with increased gluteal pain, mild to severe swelling, and erythema that is mild to severe (rare). The usual presentation begins with the patient complaining of some discomfort and tenderness in the gluteal area. On physical examination the surgeon may not see much. Over the next few days the patient develops a fever and possibly

some mild erythema; however, redness may still be difficult to discern. Over the ensuing days a localized area or a gluteus that is more swollen becomes evident, and the patient complains of increasing tenderness, especially to the touch. If this is just cellulitis, it can be treated with antibiotics; however, if an abscess is present, it will need to be drained. Usually this does not require extensive incisions; sometimes needle aspiration will suffice, along with administration of antibiotics. In other cases, if the area is not that obvious, CT-guided drain placement may be needed. If the area is obvious, a small incision is made and a drain is placed. The area can be irrigated daily with an antibiotic solution.

If the diagnosis is uncertain, ultrasound examination or a CT scan is performed. Treatment of the infection will vary: in some patients, it can be managed on an outpatient basis; in others, it may require hospitalization. A word of caution: the scan may show areas of questionable fluid accumulation, but often this is just the transferred fat. Therefore the scan has to be correlated with the clinical picture. At the first sign of possible infection, or if there is any doubt, antibiotic therapy is instituted (covering for *Staphylococcus*, *Streptococcus*, *Bacteroides*, and *Escherichia coli*).

Other Potential Complications

There have been no incidents of sciatic nerve injury, seroma, or fat necrosis among my patients. Irregularities and lumpiness have also not been problems; the injections are deep to the muscle. Patients who are simultaneously undergoing a body lift and fat transfers must be educated on the postoperative need for ambulation. If they have poor pain tolerance and refuse to move during the postoperative period, they will sit on the dissected flaps and injected fat, creating ischemia to the areas and subsequent wound necrosis. I have instituted several steps to help minimize problems:

- A mini-bowel preparation solution is given the day before surgery, with a liquid diet after 12 noon.

- Patient ambulation starts the morning after surgery. A patient who refuses to ambulate is placed in the lateral decubitus position and turned regularly, if possible.

- No more than 600 cc of fat is placed in each buttock during the first procedure. More fat can be injected later.

- The patient is positioned in a lateral decubitus position on an eggcrate mattress or air mattress bed.

Results

This 26-year-old nulliparous patient is 5 feet 5 inches tall and weighs 59 kg (130 pounds); she had round, smooth, solid silicone 290 cc implants placed intramuscularly. Liposuction of the inner legs and waist was also performed. She is shown 10 months postoperatively.

This 22-year-old nulliparous patient is 5 feet 6 inches tall and weighs 69 kg (152 pounds); she had liposuction of the abdomen, flank, back, and upper buttock. Five liters of tumescent fluid was infiltrated and 5400 cc was removed, containing tumescent fluid, blood, destroyed fat, and intact fat. Thirty percent was acceptable for transfer; 780 cc was placed in each buttock. She is shown 1 year postoperatively.

This 26-year-old patient is 5 feet 6 inches tall and weighs 64 kg (140 pounds). She has had one child. Liposuction was performed on her abdomen, flanks, back, and upper buttocks. Five liters of tumescent fluid was infiltrated and 5400 cc was removed. Fat grafting was performed in which 780 cc was placed in each buttock. She is shown 1½ years postoperatively.

This 36-year-old nulliparous patient is 5 feet 6 inches tall and weighs 70 kg (155 pounds); she had liposuction of the abdomen, inner legs, flanks, back, and upper buttocks. Five liters of tumescent fluid was infiltrated and 5400 cc was removed, containing tumescent fluid, blood, destroyed fat, and intact fat. Thirty percent was acceptable for transfer; 800 cc was placed in each buttock. She is shown 9 months postoperatively.

This 31-year-old nulliparous patient is 5 feet 6 inches tall and weighs 61 kg (135 pounds); she had liposuction of her abdomen, flanks, back, and upper buttocks. Five liters of tumescent fluid was infiltrated and 5400 cc was removed. Fat grafting was performed in which 780 cc was placed in each buttock.

Concluding Thoughts

In deciding whether to augment the gluteus with fat or implants, the surgeon first needs to determine how much fat is available for transfer. In some patients this question often cannot be answered preoperatively, because the quality and quantity is not apparent until liposuction is underway. To make a difference with fat transfers, 400 to 800 cc of fat per side should be used. The actual volume will depend on the patient's size, anatomy, and aesthetic goals. However, some generalizations can be made: small-framed individuals will require implants for gluteal augmentation; medium-framed patients present a dilemma, since they may not have enough donor fat and require implants; and patients that have a large or extra-large frame are best contoured and augmented through liposuction and fat transfers.

In intramuscular implant augmentation the size is determined intraoperatively with the aid of sizers so there will be no muscle tension at closure. Implant shape selection involves determining the muscle height-to-width ratio: a tall buttock (2 to 1 height-to-width ratio) is best augmented with an anatomic implant; a short buttock (1 to 1 ratio) is best augmented with a round implant; and an intermediate buttock (1 or 2 to 1 ratio) may require assessment of the lateral view to make the final determination.

Complications have been reduced tremendously by following three principles: the use of bilateral gluteal incisions, the use of sizers for proper implant size selection,

and proper patient selection through the use of body-frame classification to match the appropriate procedure. The implant gluteal augmentation operation has become safe, reproducible, and more acceptable to physicians but remains selective only for patients who do not have the fat to spare. The primary mode of augmentation is fat grafting, because this avoids all the possible complications that can occur with implants.

Clinical Caveats

The volume of distribution in all four quadrants of the buttock should be determined.

The V zone is evaluated for lack of muscle volume and excess fat in the presacral space.

The inner gluteal fold zone is assessed: does it have a downward 45-degree slope, a nearly horizontal character, or an upward slope?

The lateral midbuttock zone is evaluated to determine whether it is adequate, has excess tissue, or is deficient.

The presacral space–inner gluteal fold relationship is assessed to determine whether it is ideal, short, or long.

The inner gluteal crease length is measured.

On lateral view, one must determine where most of the gluteal volume lies: the upper, mid, or lower buttock.

Fat grafting is the least problematic form of gluteal augmentation.

The fat harvest should be limited to approximately 2 to 3 L.

Fat should be placed in all available layers, starting in the muscle and moving up, even in subcutaneous tissues.

Proper implant selection is important: oval, anatomic, or round.

Implant size is determined by the patient's muscle anatomy. This should be determined intraoperatively so there is no muscle tension on closure.

If the patient is still overweight, an implant is not the best form of augmentation.

Implant augmentation is best for very thin patients for whom augmentation with fat is not an option.

If possible, a bilateral paramedian incision should be used unless the patient already has a midsacral scar. In that case, the existing scar should be used.

Annotated Bibliography

González-Ulloa M. Gluteoplasty: a ten-year report. *Aesthetic Plast Surg* 15:85, 1991.

The author presents several cases that are follow-ups to the type of gluteoplasty described in the author's 1979 article in which he discusses torsoplasty and reconstruction and augmentation of the deformed gluteal region. It was found that there was considerable postoperative improvement for the patient and satisfaction for the surgeon.

Mendieta CG. Gluteoplasty. *Aesthet Surg J* 23:441-455, 2003.

Although gluteoplasty employing silicone implants has been performed for more than 30 years, little has been written about how to evaluate and reshape the area or how to select and place the various implants available. In this article the clinical anatomy of the buttocks area is reviewed, the properties of silicone elastomer gluteal implants are summarized, and an approach to evaluation and augmentation of the gluteal area involving solid silicone elastomer implants is presented. An understanding of implant shapes, sizes, and firmness will aid the surgeon in the selection of the most appropriate implant on the basis of the individual patient's gluteal anatomy. Intramuscular implant placement will result in a more natural shape, help prevent implant migration, and, most important, help reduce implant removal rates.

Perén PA, Gómez JB, Guerrerosantos J, et al. Gluteus augmentation with fat grafting. *Aesthetic Plast Surg* 24:412-417, 2000.

This study presents the authors' experience with gluteal augmentation with autologous fat grafts and liposuction methods; they review the evolution of gluteal reshaping with autologous intramuscular fat graft injections for the previous 5 years. Preoperative shape is discussed and patient evaluations, operative techniques, postoperative management, and long-term results are emphasized.

Roberts TL III, Toledo LS, Badin AZ. Augmentation of the buttocks by micro fat grafting. *Aesthet Surg J* 21:311-319, 2001.

Requests for buttock augmentation are increasing in the United States because of changes in lifestyle and fashion that emphasize the "gluteal aesthetic unit." The authors review the use of microfat grafting for enhancing the buttocks in a series of 566 patients. Buttock augmentation by microfat grafting is a safe, simple procedure. Compared with implant placement, the advantages of microfat grafting include greater flexibility in the size and placement of augmentations, less pain and faster recovery for the patient, and less risk of complications. The technique is limited only by the amount of donor fat available.

CHAPTER 86

Female Aesthetic Genital Surgery

GARY J. ALTER

The demand for female genital aesthetic surgery has increased as women and men have become more aware of genital appearance and as successful procedures have been developed to achieve patients' goals. The widespread proliferation of sexually explicit material in print and video, along with the popularity of genital hair removal, has led to women defining and seeking an aesthetic genital ideal. If a woman believes she has unattractive genitalia, she may avoid intimacy for fear of rejection or ridicule. The definition of a female genital ideal varies among individuals. Most consider the following traits as ideal:

1. Symmetrical labia minora (inner lips) that do not protrude past the labia majora (outer lips) when the woman is standing.
2. A clitoral hood that is short and nonprotruding, with few folds.
3. Full labia majora that are not overly fatty without excess hanging skin so that there is no bulge or protrusion when tight clothes are worn.
4. A mons pubis fat pad that does not protrude in clothing.

These improvements can be achieved in almost all cases. In addition to aesthetic concerns, the vast majority of women have some discomfort with clothes, exercise, or sex caused by enlarged labia minora (singular labium minus), labia majora (singular labium majus), and the clitoral hood. Hypertrophy can also interfere with hygiene.

Indications, Advantages, and Disadvantages

Enlargement of the labia minora is usually congenital. It may appear in childhood but becomes more obvious in adolescence. Occasionally, enlargement of the labia minora will increase as a result of pregnancy, birth control pills, aging, or exogenous hormones. Ideally, the labia minora should be thin, straight, light-colored, nonredundant, and symmetrical.

Labia minora reduction has traditionally been performed by trimming the protruding labia along the entire labial length. The trimming is performed using a scissor, knife, clamp, or laser. The labial edge is closed with either interrupted or running external sutures or a running subcuticular suture. This procedure has the advantages of a short operative time and of eliminating some of the dark pigmentation that is disliked by some women. However, the disadvantages are elimination of the natural labial edge, which is replaced by an incision line and often a wide, irregular, scalloped scar; difficulty creating symmetrical labia; an often unnatural transition between the labium, clitoral frenulum, and clitoral hood; the possibility of overresection

of the labia; and the potential for a higher incidence of postoperative and chronic discomfort from irritation of the scar line. Because of the disadvantages, the extended central wedge technique was developed, which may also include partial reduction of the clitoral hood.

Youthful labia majora have fullness, but overabundant fat protuberance can be congenital or may occur with weight gain. Obesity causes labia majora fat and skin enlargement. After pregnancy or weight loss, or as a result of aging, the majora can lose fat but have excess skin and wrinkling. This causes the majora to hang lower, with more redundancy. The labia majora can be reduced, depending on the cause—excess fat or skin, or a combination of both. Before hair removal became the trend, physicians traditionally placed the incisions in the midlabium. However, those scars can be very visible if genital hair is removed, so the incision line should now be placed medially in a less noticeable location.

Pubic lipodystrophy is often seen as a congenital deformity, which will not resolve with weight loss alone. The woman may complain of an unsightly bulge or protrusion; the bulge may lead her to avoid wearing tight clothes or bathing suits, citing embarrassment and loss of self-esteem. If there is no excess skin or if a lift is not necessary, pubic liposuction can be used to eliminate the fat deposit. Usually the liposuction is performed through small stab incisions in the groin creases. The upper labia majora are usually also suctioned.

The epidemic of female obesity and the trend toward massive-weight-loss procedures have resulted in the common complaints of an excessive mons pubis fat deposit and descent of the escutcheon, introitus, and labia majora. A large mons pubis fat deposit is often associated with large, protuberant labia majora as a result of fat excess and stretched skin. Weight loss rarely eliminates these deformities, so surgical treatment is required.

Traditional reduction of an enlarged mons pubis fat pad with skin descent has been a horizontal skin excision and fat resection with a skin lift. This has often been combined with an abdominoplasty. However, a skin lift is usually not adequate, because the escutcheon often descends again. A second unsuccessful lift is often attempted, which can cause an unnatural shortening of the escutcheon. Surgeons have also performed a vertical excision of pubic skin, which can lead to an unsightly T scar in the mons. A pubic lift with fat removal and tacking sutures to the rectus fascia performed through a curvilinear incision below the panniculus line gives a natural, lasting correction to the mons pubis.

Pertinent Anatomy

A clear understanding of clitoral anatomy is mandatory to prevent injury. No change in sexual sensation should occur if the clitoris is uninjured. The glans clitoris is visible underneath an overlying extension of the clitoral hood, the prepuce. The body or corpora of the clitoris is attached to the pubic symphysis by the suspensory ligament of the clitoris. The corpora diverge inferiorly and laterally and are attached bilaterally to the ischium.

A fold of skin (frenulum) extends from the ventral glans bilaterally to meet with an extension of the clitoral hood to form a labium minus. The labia minora may meet at the posterior introitus or gradually taper down.

Injury will not occur if mons fat resection is performed superior to the pubic symphysis and if labia majora fat is excised lateral to the pubic symphysis and superficial to the ischium. The glans and body of the clitoris can be palpated and protected.

LABIA MINORA

Preoperative Assessment

Labioplasty can be performed on almost any woman with enlarged labia. Labial protrusion is evaluated with the patient standing. She then is asked to lie in the lithotomy position, and the labia are examined for thickness, symmetry, and both anterior and posterior length. The clitoral hood is examined to determine protrusion, symmetry, the location of hyperkeratotic, darkened skin, the presence of extra folds, and the clitoral glans size and exposure. The posterior introitus should be evaluated for a high posterior lip or an open introitus resulting from a previous episiotomy.

A wedge or V will be excised from the most protuberant portion of each labium. Because the labia are often asymmetrical, the amount of the wedge is varied to achieve symmetry. With the patient holding a mirror and lying in the lithotomy position, the surgeon holds the amount to be excised in each hand by bringing the anterior to the posterior portion of the V together.

There may be a color mismatch between the anterior and posterior labium at the anastomosis, but this is rarely an issue with the patient if she is told preoperatively, and the color difference usually lessens with time. The surgical plan and anticipated postoperative result must be explained to the patient to prevent any misconceptions or false expectations.

Preoperative Planning

Patient Positioning and Markings

The patient is placed in the lithotomy position in the operating room; usually a general anesthetic is administered. The clitoral glans frenulum converges with the lower clitoral hood to form the labium minus; the nature of this convergence varies among women.

The anterior incision line is usually at or just posterior to this convergence. Forceps are used to determine the appropriate amount of excision in each labium to create a straight line without causing tension on the incision line or a tight introitus (which is uncommon). Markings on the opposite labium are made to achieve symmetry. The medial portion of the V extends internally to end distal to the hymeneal ring. The extended lateral markings are made in an anterior hockey-stick manner for excision of redundant lateral clitoral hood or lateral hood folds. Therefore the medial and lateral wedge excisions are asymmetrical. Usually the darkest labial skin is excised with the V. If there is extreme posterior labial asymmetry or enlargement, a second V may need to be excised from one or both sides to achieve symmetry or adequate reduction.

Operative Technique

After marking, the area is infiltrated with lidocaine and bupivacaine (Marcaine) with epinephrine. Loupe magnification is usually required to get an excellent closure and anastomosis.

The medial labium is approached first, and only the mucosa is removed. The underlying subcutaneous tissue should be preserved. The lateral skin is then excised, also removing only skin and no subcutaneous tissue.

The subcutaneous tissue is then approximated with 5-0 Monocryl on an atraumatic TF needle, in two layers whenever possible. A good subcutaneous closure helps prevent wound dehiscence or fistula formation. Any excess subcutaneous tissue is removed medially or laterally during the closure to eliminate dog-ears or an overly thick labium. The skin is then closed from distal to proximal with interrupted vertical mattress 5-0 Monocryl sutures. Running sutures can be used on the deepest portion of the medial incision line or occasionally on the lateral labium. The subcutaneous tissue of the clitoral hood is closed with a running 5-0 Monocryl suture, and the skin of the hood is closed with a running subcuticular 5-0 Monocryl suture. Minor defects may be closed with 6-0 Monocryl.

Once one side is completed, the markings on the opposite side are checked and possibly remarked for symmetry. The procedure is then repeated. In the very unusual situation in which a second wedge is required on one or both sides, this is performed after the bilateral anterior wedges are closed.

Extending the lateral labial V to the anterior hood can reduce redundant clitoral hood folds or excess lateral skin. However, if the excess folds or hypertrophic skin are more medial, the lateral V excision can stop at the lateral labium, and a vertical el-

lipse can be excised from one or both sides of the medial-lateral clitoral hood. (Excess perineal skin was also excised in this patient lateral to the posterior labia.) If there is asymmetry of the clitoral hood folds, these are adjusted accordingly. If no excess clitoral hood is present or if the patient does not want this excised, then the lateral V ends at the lateral labium or clitoral hood to prevent a dog-ear.

If the patient has redundant transverse folds of the clitoral hood, a small amount can be excised in a transverse ellipse on rare circumstances. Closure is done with interrupted vertical mattress 6-0 Monocryl. Care must be taken not to overly expose the glans, because patients can be hypersensitive or dislike the aesthetic appearance. More aggressive clitoral hood reduction requires clitoral repositioning (clitoropexy), which is beyond the scope of this chapter. Clitoral enlargement of the shaft and glans can be reduced, but this is also beyond the scope of this chapter.

The introitus should fit two fingers without significant tension to prevent overtightening. If there is a high posterior lip or overly tight introitus, a posterior midline incision may need to be made to prevent difficulty with intercourse. If the lip is incised, the vaginal mucosa is sutured to the perineal skin. This creates dog-ears bilaterally that need to be trimmed and aesthetically closed.

If a vaginal tightening procedure is performed at the same time as the labia reduction, the tightening procedure should be performed first. If the patient has very large labia requiring very large V excisions extending up to the hymen, the introitus and perineal closure distal to the hymen should not be completed until the labioplasty is finished. The large V excision can elevate the posterior lip and cause introital tightness. This is best adjusted at the time of distal vaginal and perineal closure.

Postoperative Care

The patient should use ice packs and antibiotic ointment for 2 days. Cephalosporin is given prophylactically for several days. The patient should avoid exercise for 3 weeks, but yoga and horseback and motorcycle riding should not be done for 8 weeks. Sexual intercourse is allowed at 6 weeks. Usually 80% of the swelling is resolved by 6 weeks, with all swelling and induration commonly gone in 4 months. The sutures start disappearing in 2 weeks and are usually gone by 6 weeks. The Monocryl sutures may cause itching and discomfort after several weeks; this can be alleviated with Vagisil or a very weak cortisone cream.

Problems and Complications

Complications are extremely uncommon if meticulous surgery is performed with the above sutures and techniques. Approximately 2% of patients will have a slight separation at the labial edge. Most of the visible small separations will resolve in 4 to 6 months and will not require revision. A fistula or major dehiscence occurs in less than 1% of cases. Surgical revisions may need to be performed for asymmetry of the labia minora or lateral clitoral hood, unsightly or stretched scars, separations or dehiscence of the labial edges, or fistulas. Revisions are delayed a minimum of 4 months after the initial surgery to allow healing and resolution of induration. Rarely, a patient will have some persistent discomfort lasting over several months. This is usually resolved with a several-week course of a potent cortisone cream such as clobetasol 0.05%.

Outcomes

A recent study in 407 patients revealed an average patient satisfaction rate of 9.2 on a scale of 10 (10 indicating most pleased). Patients reported improvement in self-esteem (93%), sex life (71%), and reduction of discomfort (95%), with a low significant complication rate (4%).

Results

This 23-year-old woman is shown before a labia minora reduction and lateral clitoral hood reduction.

The patient is shown 3 months after a labia minora reduction and lateral clitoral hood reduction. The appearance is very natural, with a slight color mismatch that is inconsequential.

This 50-year-old woman is shown before and 3 months after a labia minora reduction and lateral clitoral hood reduction. There is significant reduction of her labia and clitoral hood, with a natural appearance. The scars are almost invisible.

LABIA MAJORA

Women wish to recreate the youthful full labia majora. However, excessively protuberant or low-hanging labia majora can cause an unsightly bulge in clothes, often with a central crease from the introitus. The protuberance can be from either an overly fatty, full majora or a fat deficient, stretched majora with excess skin, or a combination. The woman should also be evaluated for significant mons pubic descent and pubic lipodystrophy, which could affect the approach for the majora surgery as well as results (see the next section). Labia minora and labia majora surgery can be performed in the same operation, with the minora performed first.

Preoperative Assessment

The patient's complaints are evaluated. It is helpful to have her shave on the morning before arriving for surgery, or it must be done at the time of marking. The majora are evaluated for symmetry with the patient standing and lying down in the lithotomy position. The patient uses a hand mirror to view herself during this process. Sometimes the excess may only be loose, redundant skin, whereas in others the excess may be fat. The skin or fat excess may be diffuse or more anterior or posterior.

Patient Education

The patient must be told that reduction of the majora can result in more prominence of the clitoral hood and labia minora. Occasionally, majora reduction may later lead to the patient's desire for a labia minora and/or clitoral hood reduction. She must also be told that the suture line may show a contrast between lighter and darker tissue or between coarse and fine skin. If these issues are described and shown preoperatively, the woman is usually not concerned.

Preoperative Planning

Markings

Landmarks are noted and marked, including the medial thigh creases and the lateral color differentiation of each labium. The skin excess is marked as a crescent excision from the medial labium extending from the anterior to the posterior labial commissures. The medial incision line is usually placed just lateral to the medial hairline of the labium. The amount of labial skin to be removed is determined by the amount of excision desired by each woman. However, it is usually mandatory to leave at least 2 cm of pigmented labium lateral to the lateral excision line. This usu-

ally ensures preservation of enough skin to prevent gaping of the introitus while the legs are fully abducted, which must be tested with a cotton swab pushing in the marked area. The surgeon should err on the conservative side. The crescent excision of each side is adjusted to achieve symmetry and to excise more anterior or posterior skin depending on the deformity. The medial anterior and posterior incision lines from each side do not meet in the midline but are moved laterally in a fusiform manner if necessary. Fat excision is performed in only a minority of cases. If fat is to be excised, the location and amount is noted on the markings. With fat removal, overresection must be avoided, because it gives an aged appearance.

Once the markings are made, the woman stands and the location of the lateral markings are viewed for symmetry. Cotton swabs are used to push in the excess skin or fat to coapt the medial and lateral markings, which allows the surgeon and patient to view the expected postoperative labial size. It is not unusual to perform pubic liposuction during the operation.

Operative Technique

The patient is placed in the lithotomy position. The areas of excision are infiltrated with lidocaine and bupivacaine with epinephrine. The crescent skin excisions are performed and checked for symmetry. If fat is excised in an area, the superficial Colles fascia is opened. The fat is conservatively removed with electrocautery. Meticulous hemostasis is maintained, or hematomas can occur. The skin on each side is temporarily stapled closed to check for symmetry. The wounds are then reopened.

If fat was excised, the superficial Colles fascia is closed with 4-0 or 5-0 Monocryl. The subdermal tissue is then closed with a running 5-0 Monocryl suture while including deeper Colles fascia to eliminate dead space. The skin is closed with a running subcuticular closure of 5-0 Monocryl. Drains are used only for major fat excisions.

The patient's labia majora are shown 5 months after surgery.

Postoperative Care

Steri-Strips are applied to the wound for a day or until they fall off. The remainder of the postoperative instructions are similar to those for the labia minora.

Problems and Complications

Complications are unusual. Hematomas can occur but are rare, unless a massive amount of fat is removed. The labia can swell considerably postoperatively, but this starts to resolve within a week. Significant discomfort is unusual. The most common complications are inadequate reduction or asymmetry of the skin or fat that may need to be revised in 6 months. Scars are rarely an issue if a subcuticular closure is

performed. Color contrast is not often an issue if this has been discussed with the patient preoperatively and incision placement is optimal. Persistent pain or sexual dysfunction is not likely to occur.

The worst potential complication is excessive skin excision, which can lead to a gaping introitus, causing vaginal dryness, discomfort in clothes, and an aesthetic deformity. This complication is more likely to occur if a medial thigh lift has been or will be performed, because the thigh lift Colles fascia tacking sutures can loosen, causing posterior migration of the thigh skin, thus pulling the majora and opening the introitus. If a medial thigh lift is contemplated or recent, skin excision should be even more conservative.

Outcomes

No series of labia majora reduction has been published. However, patients have expressed that they are extremely gratified with their result if their expectations were realistic preoperatively.

Results

This 55-year-old woman is shown preoperatively and at 5 months postoperatively (she is also shown on pp. 3108-3110). She underwent pubic liposuction and labia majora skin and fat reduction.

MONS PUBIS LIFT

A natural-appearing mons reduction and lift can be achieved with a horizontal skin excision; undermining of the mons fat pad; liposuction of the mons pubis, upper labia majora, and inguinal fat; and fat excision of the residual deforming fat pad. It is imperative that the fibrofatty tissue of the pubic skin flap be tacked to the rectus fascia to prevent recurrent pubic descent.

Preoperative Assessment

The amount of pubic fat and mons descent is evaluated first with the patient in the standing position. The enlargement and protrusion of the labia majora are also noted. If a panniculus is present, it is elevated to determine the amount of pubic skin that needs to be transversely excised. The anterior labial commissure should be at the pubic symphysis. The actual skin excision required is usually no more than several centimeters, because the pubic skin will modestly contract as the fat is removed. Overresection of skin can elevate the commissure too high and give an unnatural appearance. The skin incision is placed just below a pannus fold or at a previous abdominoplasty scar line. The skin crescent excision may remove a small amount of the upper pubic hair. The length of the incision is usually only long enough to eliminate the excess skin but can rarely extend to the anterior superior spines. The appearance of the labia majora with the elevation of the fat pad is also observed, and the amount of fat removal is estimated, if needed.

Preoperative Planning

Patient Position and Markings

With the patient in the lithotomy position, the labia majora are evaluated for liposuction or marked for skin or fat excision if this is to be performed simultaneously. The procedure is the same as outlined previously.

The patient is placed in the supine position if only a pubic lift is performed. If labia majora skin or fat reduction is to be performed, she is placed in the lithotomy position, with the abdomen and genital region prepared.

Operative Technique

The upper incision is made and carried down to the rectus fascia. The pubic flap is elevated to the pubic symphysis between the external inguinal rings. More extensive dissection is usually not necessary.

The inferior incision is then made, and a modest amount of pubic fat is excised. Infiltration of the mons, upper labia majora, and inguinal region is performed with tumescent fluid.

Liposuction of upper labia majora, pubis, and inguinal areas leaving 1-2 cm of fat on skin flap

The pubic flap is liposuctioned to a thickness of 1 to 2 cm. The lateral areas are suctioned to prevent a concavity, and the upper labia majora are suctioned. Liposuction of the flap is preferable to open excision of the pubic fat, because it preserves the fibrofatty tissue used for tacking. If the labia majora fat is modestly increased, liposuction of the entire majora can be performed at this time. If labial fat is to be excised from above, open resection is done, followed by bilateral insertion of closed suction drains.

To maintain the lifted position of the mons pubis, rows of tacking sutures of 1 Ethibond on a CTX needle are placed from the fibrofatty subdermal tissue of the flap to the rectus fascia. The first row of three sutures is usually placed 1 to 2 cm cephalad to the anterior labial commissure to the rectus fascia just cephalad to the pubic symphysis and between the external inguinal rings. Mild dimpling can occur and is probably necessary to maintain the lift. These are the crucial sutures, and several attempts may be required to prevent an abnormal pulled appearance of the majora, to minimize dimpling, and to achieve symmetry.

Usually two more rows of three sutures are placed. A closed suction drain is placed from the pubic symphysis along the right lateral sutures, and then under the subcutaneous closure. The subcutaneous tissue and skin are closed. The thickness of the subcutaneous tissue on each side of the incision line should be equal, so liposuction of the lower portion of the abdominal skin flap may occasionally be needed. Rarely, excess abdominal skin may need to be resected to prevent it from overriding the pubic area.

This patient underwent a pubic lift, labia majora liposuction, and bilateral Z-plasties to eliminate restrictive medial thigh bands. She is shown preoperatively and immediately after labial liposuction and a mons lift. If the labia majora skin and fat are to be excised, this is performed at this time (see the labia majora section).

Postoperative Care

The patient's drains are removed when drainage is minimal. The patient is instructed to use ice packs on the majora for 2 days.

Problems and Complications

The patient should be told that there might be some concavity in the pubic area. However, liposuction of the pubic flap with conservative pubic fat resection along with lateral liposuction helps prevent that. Excess elevation of the pubic area can result in an unnatural anterior labial commissure and a short escutcheon. This is uncommon if skin resection is conservative.

If the patient has had a previous inner thigh lift, labia majora skin excision should probably not be performed at the same time as the pubic lift. Theoretically, the skin between the majora incision and the inner thigh may be at risk if the pubic resection is performed. Instead, labia majora liposuction or fat excision through the pubic wound can be done first, followed by a later procedure for additional excision of labia majora fat and skin, if necessary.

Outcomes

Patients are generally extremely happy with elimination of the pubic protrusion. It is uncommon to have an unhappy patient as long as the limitations and potential results are explained and shown to the patient preoperatively. The need for recurrent pubic lift surgery is very uncommon.

Results

This 23-year-old patient (also shown on p. 3112) is seen before surgery and 4 months postoperatively.

This 34-year-old woman had lost 91 kg (200 pounds), and an abdominoplasty with an attempt to decrease the pubic mons fat pad had been performed previously. The markings show the amount of pubic skin to be excised and the previous abdominoplasty scar. The lateral incision lines on the labia majora are checked for symmetry. The markings for the labia majora skin excisions are shown, which do not cross the midline. The pubic lift was completed, and the closure after labia majora skin excisions and pubic lift are shown.

The patient is shown preoperatively with a bulging pubic fat pad and hanging labia majora. Ten months postoperatively, an excellent result is seen. She could benefit from more pubic liposuction, but she is not concerned about this.

Concluding Thoughts

Aesthetic genital surgery can be very successful if the guidelines are followed meticulously. As more women become aware that safe, successful operations are available, the number of procedures performed will continue to increase.

Clinical Caveats

During preoperative assessment for all procedures, the patient should hold a mirror while she is shown the tissue to be excised and her expected postoperative result is discussed.

Labia Minora Reduction

The excision should not be closed with tension.

A good subcutaneous closure, usually in two layers through most of the length, is essential to prevent dehiscence. The labium is thus closed in four layers.

5-0 Monocryl on an atraumatic TF needle is ideal to prevent a tissue reaction and trauma that can lead to wound separation.

Vertical mattress sutures at the leading edge of the labium minus help to prevent wound separations.

The surgeon should confirm that two fingerbreadths can be inserted in the vagina.

The glans clitoris should not be overexposed if some of the clitoral hood is being excised vertically or horizontally. The glans exposure should remain the same as before surgery unless the patient requests otherwise.

Labia Majora Reduction

The eventual scar line should be as inconspicuous as possible, usually just lateral to the medial hairline.

The symmetry of the markings should be checked with the patient both standing and lying down; the appearance of the labia can be assessed by imbricating the marked areas with cotton swabs.

Overresection of the skin must be avoided, because this can cause a gaping introitus, especially if an inner thigh lift has been done or is contemplated.

A subcuticular closure should be used.

Continued

Clinical Caveats—cont'd

Mons Pubis Lift

The anterior labial commissure should not be overelevated.

Care must be exercised so that the escutcheon is not too narrow.

The pubic flap is primarily thinned by liposuction. An adequate amount of fibrofatty tissue should be left on the flap to prevent a concavity. The peripheral areas are liposuctioned for wound contouring.

Usually three horizontal rows of three symmetrical, strong tacking sutures are placed from the pubic flap to the rectus fascia.

The thickness of the two sides of the skin closure are matched and adjusted as needed.

CHAPTER 87

Evaluation and Treatment of Iatrogenic Deformities

SYDNEY R. COLEMAN

Structural fat grafting is an essential tool for all aesthetic surgeons performing liposuction, because it provides a successful way to treat iatrogenic liposuction deformities. Patients with liposuction deformities were the first patients in my practice in whom I attempted fat grafting and therefore the patients with whom I have the longest experience. Unlike the use of fat to rejuvenate the hand, successful treatment of surface irregularities in the body requires a three-dimensional visualization of the problems and solutions.

Aesthetic Considerations

Any surgeon performing liposuction will undoubtedly experience the most common complication of liposuction—superficial surface irregularities. Some are exaggerations of preexisting irregularities, some consist of cellulite, and some are newly created. The thigh and abdomen are particularly prone to irregularities. Postliposuction iatrogenic deformities are not limited to surface irregularities. Changing the relationship between a woman's thighs, hips, and abdomen can result in unnatural and even bizarre proportions.

In 1987 I began treating iatrogenic liposuction deformities with fat grafting, primarily focusing on correction of surface irregularities. As I became more proficient at fat grafting, I began to address corporeal proportion to restore a more natural aesthetic symmetry after liposuction.

This 30-year-old woman presented 2 years after liposuction to her lateral thighs, buttocks, and love handles. She was distressed by the deepening of her buttock crease, which now wrapped around her thigh. She felt that her legs looked shorter and her buttocks bigger and more ptotic after the procedure. She also noticed that her body appeared boxy and less feminine. When she complained to the plastic surgeon about

the appearance of her buttocks, she discovered that he had purposely deepened her buttock crease to create a more aesthetic “smiling” crease.

The patient is shown 3 years after her second procedure, which restored a more normal appearance to her body. Additional fat was removed from her waist, upper hip, and lateral buttocks and placed into her buttock creases and lateral thighs to create a more feminine and natural relationship of the waist, hip, and thigh. By filling in the deepened buttock crease and slightly expanding the thighs, a more normal buttock-thigh interface was reestablished. By restoring the continuous flow of the buttock into the thigh, a more attractive, youthful line of the leg was restored.

Patient Selection

Patients who present with iatrogenic body deformities have usually had previous experiences with aesthetic surgeons, and they view these experiences as negative. Their perception of their bodies is colored by that experience, and it is often difficult to assess how realistic these patients are about their current appearance as well as the degree of satisfaction they will attain with treatment.

The aesthetic surgeon should not agree to perform a correction unless he or she has a reasonable expectation that a positive correction of the patient's deformity can be done without creating unacceptable new problems (such as donor-site deformities). Furthermore, the surgeon should believe that the positive correction will be demonstrable on photographs and that the patient will be able to appreciate the positive change. It should be clearly explained to the patient that new deformities might be created by harvesting fat to correct the current irregularities.

Patient Education

These patients need to be prepared for the result. For major deformities, I warn patients that it may take as many as four procedures to attain a result that they will find acceptable (although I have never performed more than three procedures on any one patient's body). I explain to the patient that the first procedure for a major defect is to restore volume; the second is to smooth out the area with "finishing touches." On an extremely rare occasion, a patient may desire a third procedure to smooth the area even more. For smaller irregularities, one procedure is often sufficient.

Patient Evaluation

The most important step in correction of iatrogenic deformities is analysis of the defect. If the surgeon cannot adequately demonstrate a deformity on film, it will be almost impossible to show that the procedure has produced a positive change.

Photography for corporeal proportion is relatively standard, but photographic techniques to demonstrate surface irregularities are more challenging and require a different approach. When patients see their bodies in standard photographs, they often comment that the image does not accurately portray the full extent of the surface irregularities they see when they look at their unclothed bodies. I have come to realize that the primary reason for this discrepancy is that patients are most often looking down at their bodies with downlighting when they see these irregularities, whereas standard photographs are taken without this elevated perspective and with more diffuse light. Therefore it is difficult to appreciate patients' deformities with the standard views that plastic surgeons routinely obtain.

After much experimentation with lighting, I have finally developed a system of photography for analyzing corporeal defects to more accurately reflect what the patient sees and wants corrected. This system came about when one of my patients insisted that I take photographs of her body while I was standing on a stool so that the camera was a few feet above her. From this "bird's-eye" perspective, we were both much better able to appreciate the extent of her body surface irregularities than from any of the standard views.

With this bird's-eye view of a patient, the defect in her left buttock is clearly visible, in the same way that it is visible to her as she looks over her shoulder or in the mirror with downlighting.

Even large irregularities can be difficult to discern in the standard photograph taken of this patient compared with the bird's-eye view. I now stand on a stool and obtain approximately 10 views of a patient's body for almost any corporeal procedure that I perform. By shooting from a bird's-eye view, I can more effectively see the problem that the patient wants corrected.

After the patient is marked to demonstrate the areas of harvesting and placement of structural fat, I then photograph the patient standing with the marks. Before the procedure begins, I have the photographs printed to compare the marked and unmarked photographs, both with the patient standing. With the photographs placed next to each other, I can more accurately determine the relationship of the marks to the actual deformity while I am operating on the patient, who is in a supine or prone position.

Technique

Anesthesia

Epidural and occasionally general anesthesia are most commonly used. No solution is placed into the areas to be infiltrated.

Incisions

When harvesting from the back, sacrum, or hip, the lateral sacral depressions are used as the main incisions. Incisions into this anatomic structure are much better tolerated than incisions anywhere else in this region.

Infiltration Cannulas

The syringes are connected to cannulas, which range from 18 to 16 gauge and vary in length from 7 to 15 cm. I prefer to use the shorter cannulas (usually 9 cm), but to avoid making too many incisions, I will often switch to a 15 cm cannula to extend placement from any one incision. When using the 15 cm cannulas, I prefer to use the thinner cannulas. I will switch to a 16-gauge cannula if there is much resistance. I alternate between straight and curved cannulas, depending on the curvature of the underlying structures.

The body is the only place that I use 3 cc Luer-Lok syringes for infiltration of fatty tissue. I fill the 3 cc syringes with 2.5 cc of refined fat to make them easier to manipulate. Unlike the 1 cc syringes, these syringes can be reused repeatedly without the plungers sticking. The technique of placement in the body differs from that described for the face and hands in that slightly larger amounts are placed with each pass, but no more than 0.25 cc is intentionally placed in a single withdrawal.

Level of Infiltration

The level of infiltration depends on the desired outcome:

Fat is layered into the deep planes for large contour changes to the thighs or buttocks. In those deeper fat planes, especially if any tissue is placed into muscles, the thicker 16-gauge 15 cm style I cannulas are used. The blunt large cannulas minimize the possibility of damage to vessels and nerves in the muscles. More tissue is placed superficially to fill a specific groove or depression. Placement starts in the immediately subcutaneous plane and infiltrates layer by layer to a deeper plane, specifically feathering as the placement deepens.

Volume Ranges

Volumes for correction of corporeal deformities vary from 1 cc placements into minuscule irregularities to as much as 300 or 400 cc into a deficient thigh, buttock, or arm.

Procedure

This 60-year-old patient presented with a depression that developed after she had multiple injections of steroids into her left hip. A significant defect is visible from the bird's-eye view, whereas I could barely see the problem in most of her conventional photographs.

The procedure is planned on tracings of the patient's body in many views. The plan devised for this patient was to remove tissue above the defect and refine it, and then place it into the depression.

The areas of planned removal were marked with a purple marker, the areas of planned placement of the refined fatty tissue with a green marker, and the planned incision sites with red markers.

This patient has already had tissue harvested from her right side and her upper love handle on the left. The first step in correcting the depression was to remove tissue above the defect to flatten the surface superior to the defect and provide additional harvested tissue to place into the defect. I began harvesting the portion nearest the contralateral incision using a 23 cm straight harvesting cannula with access through the contralateral sacral incision. I then switched to the ipsilateral incision and continued the removal of tissue laterally using either a 15 or 23 cm straight cannula.

To decrease the number of incisions that are needed to effectively remove subcutaneous tissue in the torso, I began using curved cannulas connected to my 10 cc syringes. A gently sloping curve on a cannula allows me to follow the natural curves of the body. For example, in this patient I could follow her body contours all the way to the far flank and hip from a sacral incision with a 23 cm curved cannula; 100 cc was removed from this patient's right love handle and 70 cc from the hip above the depression.

Placement into the defect begins with a style I blunt, 15 cm infiltration cannula through the ipsilateral sacral incision. This longer cannula allows placement from a slightly more distal incision. The placement begins deep and progresses in layers to a superficial level to create an integrated volume. The barrel of the cannula is firmly grasped between the fingers (middle, ring, and little) and the thumb while the cannula is inserted into the incision and advanced through the tissues. I use my index finger (or thumb in some situations) to push on the plunger while the cannula is withdrawn. *Fat is forced through the cannula into the donor site only as the cannula is removed, not while it is advanced.*

Numerous layers of fat are infiltrated in the deep tissues, gradually moving superficially to place a layer immediately subdermally. In the more superficial planes, the surgeon must pay special attention to avoiding linear placement or lumps. Placement in the immediate subdermal plane is especially important in patients with atrophy from steroids or other injections. I try to approach most areas for infiltration of fatty tissue in the body and face from at least two directions to provide more structural integrity to the placed tissue. In this instance I made an incision to allow placement perpendicular to the previously placed fat. After the incision with a No. 11 blade, I often open the depth of the incision with a small scissors or style III cannula. Placement continues, emphasizing the area of greatest deficiency in the central circle above, and feathering out into the surrounding areas.

The placement again begins deep against fascia and muscle through to the most superficial planes. An attempt should be made to disrupt an adhesion that causes surface dimpling or an isolated depression. This should be performed after most of the fat placement has been attempted to avoid creating unstable tissue planes in which the fat can migrate. I recommend disruption of subcutaneous adhesions or scars with a V-dissector. In the body, a 14- to 16-gauge cannula and a 15 cm cannula may be more useful and effective.

Posttreatment Care

One or two layers of Microfoam tape are placed over any areas into which fat has been grafted. Bulky dressings or foam rubber is never positioned over grafted areas. However, Reston foam can be placed over areas that are suctioned on the body to relieve pressure on grafted areas. Over the Microfoam tape and Reston foam, a girdle or abdominal binder can be placed to apply gentle pressure on the Reston foam and to secure the Microfoam tape.

If grafting is performed in the buttock crease or around the sacrum, the surgeon must consider positioning of the patient after the procedure. Because the ischium is weight bearing when the patient is sitting, he or she is instructed not to sit directly on the “sitz bones.” Rather, the patient should sit far forward or lean backward to distribute the weight while sitting so that the weight is not directed to the area of recent grafting. Because the sacrum is weight bearing when the patient is supine, the patient should be encouraged to lie on the opposite side, if possible, after grafting around the sacrum. Patients are also asked to wait at least 2 weeks before massaging the recipient sites to allow sufficient time for grafted tissues to become more stable.

Complications

Undercorrection and overcorrection are the two most frequent complications after corporeal fat grafting. Friction from the many passes of the harvesting and infiltration cannulas can create incisional complications, such as hyperpigmentation and depressed scars. Use of the lipids decanted after centrifugation to lubricate the cannulas can significantly improve the appearance of the incisions. Paresthesia and transient anesthesia are also common in both the recipient and donor sites. Patients rarely complain about them for more than a few weeks.

Results

Many of the patients who are seen for correction have subtle surface irregularities requiring only smoothing without significant volume replacement. This 35-year-old patient presented 3 years after lateral thigh liposuction complaining of minor irregularities.

Because she had almost no viable donor sites, it was possible to harvest only minimal amounts of tissue. Therefore only 30 cc was placed into her right lateral thigh irregularities in the areas demonstrated above.

The patient returned at 2 years and 3 months after the only procedure. The modest amounts of structural fat grafting resulted in significant improvement and great patient satisfaction.

Clinical Caveats

The most important step in correction of corporeal deformities is analysis of the defect. A photograph from a bird's-eye view is invaluable for accomplishing this purpose.

To lessen any potential donor defect, the surgeon should minimize the amount of fat suctioned in any one area.

Use of the oils decanted after centrifugation to lubricate the cannulas can significantly improve the appearance of the incisions.

CHAPTER 88

Correction of Contour Deformities After Liposuction

KRISTOFFER NING CHANG

With the introduction and popularization of *suction-assisted lipectomy* (SAL) in the 1980s, the concept of body contour surgery was dramatically transformed, offering surgeons a new tool to improve outcomes and reduce morbidity. Since that time, subsequent refinements and developments, including the use of wetting solution, large-volume liposuction, *ultrasound-assisted liposuction* (UAL), and *power-assisted liposuction* (PAL), have further enhanced our ability to contour the body. Today, liposuction's popularity and appeal have made it one of the most frequently performed aesthetic operations in the United States. Despite the excellent results often obtained with liposuction, this procedure is not trouble free and may produce aesthetically unsatisfactory results. Aesthetic problems resulting from liposuction can be grouped into four general categories:

1. Skin problems
2. Surface or contour irregularities
3. Disproportions
4. Skin excess

Skin problems include pigmentation changes, discoloration, loss of smoothness and sheen, textural changes, atrophy, wrinkling, and scarring. Surface or contour irregularities include visually distinct depressions, grooves, waves, dents, divots, dimples, ridges, and protuberances. Aesthetic disproportion is characterized by altered proportion in various parts of the body, rendering a disharmonious, displeasing look. For example, excessive removal of fat of a woman's thighs may result in an emaciated or a masculinized appearance. Excessive skin results from a discrepancy between the overlying skin envelope and the underlying subcutaneous tissue and fat. The junction of the lower buttock and upper posterior thigh is an area prone to this type of problem.

These changes are referred to as *postliposuction contour irregularities* or *iatrogenic deformities*, and they are familiar to any surgeon who performs liposuction. This chapter presents postliposuction deformities and strategies for their prevention and treatment.

Avoiding Deformities From Liposuction Procedures

A number of variables influence the outcome after liposuction and should be carefully considered when planning liposuction. These variables include the patient's age and skin condition, the composition and extractability of the fat, the equipment to be used (SAL, UAL, or PAL), the infiltration of wetting solution, artistic planning and surgical execution, and postoperative care. Careful planning is the key to preventing postliposuction deformities. The surgeon must understand the potential pit-

falls to be avoided and must individualize treatment to take into consideration the particular anatomic situation for each patient. Major factors that contribute to poor aesthetic results include overresection, underresection, removal of fat from the wrong location or from the incorrect depth of the subcutaneous layer, excessive fibrosis, scarring, loss of tissue elasticity and support, and skin excess.

Factors That Contribute to Poor Aesthetic Results

Overresection

Although we have strategies for correcting problems related to liposuction, it is always best to avoid them. Understanding the causes of these problems will help prevent them. Contour irregularities are among the most common deformities after liposuction. A common cause of these deformities is overresection of adipose tissue, which may result from employing a cannula that is too large or by making too many passes with the cannula in the same location. In some patients, especially fair, thin-skinned women, the adipose tissue may be loose and prone to overresection. The use of wetting solution containing epinephrine and lidocaine promotes hemostasis, provides analgesia, and makes the fat more easily removable. When an excessive amount of wetting solution is used in an area where the fat is loose and nonfibrous (for example, the buttocks or lateral thighs), fat extraction can easily exceed what is needed to achieve the desired result. Excessive infiltration of wetting solution, combined with the use of the cannula in the subdermal layer, may result in diffuse, multicentric contour irregularities. To ensure a good surgical outcome, there must be a smooth, unscarred layer of adipose tissue remaining beneath the skin and dermis.

In some patients, the aesthetic limit of fat extraction may be exceeded. Too much fat removal from the thighs may transform a desirable female shape into a more masculine appearance. The midsection of the medial thigh is particularly susceptible in this regard. Overresection may occur when the underlying bony prominence causes the surgeon to erroneously assess the remaining amount of adipose tissue to be removed. The medial condyle of the femur can mask overresection while the patient is in a supine position with the knee extended. This soft tissue deficiency becomes evident when the patient assumes a sitting position.

Uneven Resection

Uneven resection may occur where more fibrous adipose tissue is juxtaposed with looser adipose tissue. For example, in the periumbilical area, dense subcutaneous tissue around the umbilical stalk changes into the softer adipose tissue of the lower abdomen. Similarly, a preexisting abdominal surgical scar may cause interference with smooth fat extraction near the scar. Careful patient examination and planning for these anatomic variants can help prevent potential problems in these areas.

Incision Placement

Suboptimal incision placement may also yield unsatisfactory results. Ideally, an incision should permit easy access for execution of a series of unhindered, smooth, and radiating cannula movements appropriate for the three-dimensional configuration of the adipose tissue to be modified. When the cannula is torqued, forced to go around a curved surface, or its movement is impeded, the results may be suboptimal. To ensure smooth coverage of the area to be aspirated, two incisions may be placed 90 degrees from each other to allow the surgeon to make crisscrossing patterns. In circumferential liposuction or liposuction of extensive body surfaces, grid-pattern markings of variable sizes can be drawn on the skin surface intraoperatively to assist with placement of incisions and to facilitate unimpeded cannula movement.

The Level of Subcutaneous Tissue

Removal of adipose tissue from an inappropriate subcutaneous level may contribute to unsatisfactory results. For example, when fat is removed from the deep subcutaneous layer of the lower buttock and the upper posterior thigh region, support is lost and the buttock becomes ptotic. Improvement of the upper posterior thigh (subgluteal region) and the anterosuperior knee is accomplished by removal of more superficial fat.

Markings

The body's contour changes as the patient moves from a standing to a recumbent position, or when wetting solution is infiltrated. These changes must be considered when markings are being made preoperatively. The appropriate surgical markings guide the surgeon to prevent compromise of the extraction of fat. Lack of proper feathering at the periphery of the liposuction site may lead to a visible demarcation between the treated and untreated areas.

Use of Ultrasound-Assisted Liposuction

When UAL is being used, care must be taken to carefully regulate the amount of ultrasound energy applied. Excessive ultrasound energy may result in overresection, prolonged edema, and tissue damage from mechanical impact or the thermal effect.

Compression

Appropriate application of postoperative compression is important to prevent deformities. Uneven compression may lead to temporary or permanent deformation of the skin and subcutaneous tissue. Prolonged and tight postoperative compression may accentuate tissue ischemia associated with the use of epinephrine and tissue trauma from fat extraction, thereby resulting in more fibrosis and scarring.

Liposuction is a very effective tool for body contouring. Its successful execution is highly dependent on sound surgical judgment based on careful patient evaluation, meticulous preoperative planning, an understanding of anatomic landmarks, and knowledge of one's own surgical skills.

Secondary Procedures for Treating Postliposuction Deformities

Secondary procedures are performed after liposuction to remove residual fat excess and contour irregularities. Residual fat excess with a smooth, normal-appearing contour is amenable to additional liposuction. Protuberances in contour that appear visually distinct and do not blend into the surrounding surface contour require additional liposuction. Minor contour irregularities can be treated by limited additional liposuction, which is often performed under local anesthesia. The more severe and complex cases of postliposuction contour irregularities require a systematic approach that includes combinations of the following:

1. Liposuction of areas of protuberance
2. Liposuction around the areas of depression
3. Simultaneous fat grafting
4. Dermolipectomy for redundant skin

The technique of corrective liposuction and fat grafting has been available since the late 1980s. It has the advantage of being simple and safe. Fat collection, processing, and injection require commonly available supplies and instruments. Most patients have ample amount of fat available for harvesting to further modify and improve the contour.

Indications and Contraindications

Autologous fat grafting is indicated for the replacement of volume deficiencies and for filling postliposuction irregularities and indentations in the thighs, abdomen, hips, waist, buttocks, chest, and arms.

Patient Profiles

Liposuction of this 54-year-old woman's thighs and abdomen resulted in indentations in her anterolateral thighs, distal medial thighs, left groin, and lower abdomen. She is a good candidate for corrective liposuction and fat grafting because she has the following characteristics: (1) abundant subcutaneous fatty tissue around areas of depression, (2) gentle slopes in areas of indentation, (3) preservation of good skin quality in the areas of indentation, and (4) an absence of dense subcutaneous scarring.

Some patients develop extensive skin changes and subcutaneous fibrosis with multiple diffuse indentations. These problems are less responsive to corrective liposuction and are better treated with fat grafting.

Dermolipectomy is indicated for patients with redundant skin or extensively affected skin. This 45-year-old woman is a candidate for dermolipectomy. She developed loose skin in the medial thighs with uneven contours in the medial and anterior thighs after liposuction.

She was first treated with corrective liposuction and fat grafting, which was followed by medial thigh dermolipectomy after 1 year and 8 months. Postoperative results show a smooth contour and less flaccid skin 10 months later.

The same patient also developed an extra crease in the left upper posterior thigh and buttock junction after her original liposuction. This deformity was improved with posterior thigh dermolipectomy, which was an extension from and continuous with the medial thigh dermolipectomy.

The location of redundant skin determines where dermolipectomy is indicated. Dermolipectomy procedures include but are not limited to medial thigh lift, transverse flank-thigh-buttock lift, lower abdominal dermolipectomy, abdominoplasty, upper abdominal dermolipectomy, and brachioplasty.

In 2001 Saylan described *liposhifting* as a technique for the treatment of postlipoplasty irregularities. More recently, Wall has advanced the technique he refers to as *separation and fat equalization* and applied its use to both secondary and primary lipoplasty. In this technique, the fat is separated with a cannula that has an expanded, basket-shaped tip.

The fat is shifted and redistributed by manual massage and back-and-forth cannula movements without suction. Thus the fat is redistributed and equalized between areas of relative excess and deficiency. Wall's technique uses a power-assisted device. The fat transfer is internal, without leaving the body.

Liposhifting complements the “external” fat transfer technique. It does not replace external transfer of fat from a distant site if there is a significant deficiency of fatty tissue. In some cases in which the deformity is irregular, multicentric, and complex in shape, or if there is tight and localized subcutaneous scarring, liposhifting may have some unique advantages. Certainly liposhifting and fat grafting by an external route can be combined for synergistic effect.

Case courtesy Simeon Wall, Jr., MD

This 30-year-old woman had a history of prior liposuction of her circumferential thighs, with a contour deformity in the mid-buttock extending into the right lateral thigh. *SAFELipo* of the circumferential trunk and thighs was performed, with uniform foam compression postoperatively to maintain a smooth contour. She is seen 1 year postoperatively.

Case courtesy Simeon Wall, Jr., MD

This 39-year-old woman had a history of prior liposuction of the trunk, thighs, and buttocks, with a resultant deep contour deformity in the upper lateral buttock. *SAFE-Lipo* of the circumferential trunk was performed, using some liposhifting to further equalize the contour. Uneven (nonuniform) foam compression was used postoperatively, consisting of 1-inch Reston foam with a cutout in the center to allow the depressed area to expand and maintain the shifted fat. Today, with a defect that is particularly depressed and/or scarred down such as this, I usually add some fat grafting to the standard fat equalization/fat shifting (*SAFE-Lipo*) techniques to ensure that these areas are fully elevated. This approach is in contrast to wider areas of uneven contour, where correction does not usually require formal fat grafting, as seen in the previous case.

Clinical Anatomy of the Subcutaneous Adipose Tissue

For liposuction, the extractability of fat varies, depending on the individual, sex, and anatomic location of the fat. In general, it takes more effort to extract fat in men than in women. A ranking of body regions in order of increasing difficulty of fat removal includes the medial knees, buttocks, lateral thighs, central lower abdomen, medial thighs, upper arms, hips, calves, ankles, flanks, chest wall, and back.

The subcutaneous adipose tissue of the trunk and extremities is organized into a continuous fatty layer or superficial layer and a localized, deep fatty layer that is also present in the abdomen, paralumbar area, and gluteal–upper thigh regions. The subcutaneous fascia, or superficial fascial system, is the fibrous connective tissue network that, depending on the location, contains single or multiple horizontal membranous layers and vertically oriented extensions attaching to the subdermal layer above and the deep fascia layer below.

ZONES OF ADHERENCE

Varying zones of adherence of the superficial fascial system extend over the trunk and extremities. The encased fat produces bulges, valleys, plateaus, creases, and folds. The most adherent zones are found in skin creases and valleys, such as the inframammary fold, groin crease, gluteal crease, the anterior and posterior midline, and lateral gluteal depressions. Zones of least adherence are the bulges of the truncal area and the extremities, where the superficial fascial system forms a roof over the localized deep fatty layer. Intermediate zones of adherence exist in all areas of the trunk and extremities without significant deep fat. Surgical alteration within certain zones of adhesion, such as the lateral gluteal depression and buttock crease, may predispose the patient to postliposuction contour irregularities.

Extractability of the fat depends on its density and the strength of its encasing connective tissue. Loosely organized deep fat tends to be more easily removed than the more compact superficial fat. In lipoplasty, depending on the aesthetic goals, the superficial fatty layer and the deep fatty layer are targeted for fat extraction. However, it is important to leave a smooth, healthy layer of fat beneath the skin after liposuction. To treat postliposuction contour irregularities, corrective liposuction and fat grafting are directed toward modification and restoration of the superficial and deep fatty layers, as needed.

Preoperative Assessment

During the consultation with a patient regarding secondary procedures to correct postliposuction contour irregularities, the surgeon obtains information about the patient's preoperative body appearance, the changes that resulted from the primary surgery, any postoperative complications, the anesthetic technique used, and details of the surgery, if known.

The areas of fat excess and fat deficiency are located, the ideal contour is visualized, and sites of fat harvesting are determined.

Physical examination includes assessment of the thickness of the subcutaneous fatty layer with a skin pinch test. Underlying musculoskeletal contour is assessed by palpation as the patient contracts and relaxes the muscles. Laxity and sagging of the skin are evaluated by lifting the skin up against gravity and observing the body contour as the patient assumes upright, reclined, sitting, and flexed positions.

The surgical plan is discussed with the patient. Areas of fat excess and deficiency can be marked on the patient's skin as the surgical plan is discussed. Photographs are taken during the initial visit to identify areas for correction. Variable retention of the fat graft, realistic expectations, limitations, financial cost, and the potential need for additional procedures are discussed fully with the patient. For major contour irregularities, both early (3 to 6 months) and late interventions appear to be effective.

Preoperative Planning

Markings

A detailed topographic contour map is essential to the planning and execution of corrective surgery. Photographs without flash, using only overhead ceiling lighting, are routinely taken. Areas of maximal depression, areas of maximal protuberance, and the adjacent transition zones are indicated precisely. Markings should reflect differences in the amount of fat to be removed and injected in different areas.

Although skin markers of different colors provide added contrast, all markings can be performed with a black skin marker. Areas of maximal depression are colored black. Areas of maximal protuberance or fat excess are marked with multiple Xs or crosshatching. Transition zones between the two extremes are left unmarked. For complicated cases, I routinely perform the markings the day before surgery. This gives the patient ample opportunity to fully inspect the operative sites, including the donor sites, and ensures that the patient and the surgeon agree on the surgical plan.

The marking is performed with the patient in a standing position. Digital photographs of the surgical markings are used intraoperatively. Areas of maximum depression may be tattooed with methylene blue at the start of surgery to help maintain accurate surgical markings intraoperatively.

Incision Placement

Cannula entry sites for corrective liposuction should be selected to ensure the most direct approach to the areas to be aspirated. Attempts to hide the incision may compromise cannula movement and the final results.

Operative Technique

For fat harvesting, infiltration of wetting solution is minimized or avoided to obtain fat of maximum solidity. Lidocaine 0.25% with 1:400,000 to 1:800,000 epinephrine is injected with a 22-gauge spinal needle. Infiltration into the operative site requiring correction is minimized or avoided to facilitate intraoperative evaluation of the contour as fat is aspirated or added. Patients undergoing more extensive and complex procedures are given a general anesthetic.

The fat is collected by pouring directly from the patient end of the liposuction tubing or with an interposed sterile specimen trap. Pretunneling before fat removal facilitates localization of the excess fat, helps to establish correct cannula pathways, avoids unwanted fat removal, and maximizes the accuracy of fat extraction. It is important to avoid excessive or full vacuum pressure when harvesting fat for reinjection. I limit the vacuum setting to 26 to 28 mm Hg.

The fat is allowed to settle and the liquid portion is discarded. No special processing is required. If the fat is dilute or if the amount is small, a centrifuge or absorbent gauze can be used to concentrate the fat. A blunt-tipped cannula without suction is passed beneath areas of dense subcutaneous adhesion to make multiple tunnels before fat injection.

Fat is injected with a small blunt-tipped cannula with an outside diameter of 1.5 to 1.8 mm. A blunt-tipped cannula is preferred, because it is less likely to cause bleeding during fat injection. Alternatively, a 16- or 18-gauge hypodermic needle may offer the advantage of more precise and effective fat deposition, especially in densely fibrotic areas.

The process is repeated. The fat is injected in small increments, in multiple passes, and at multiple depths. The pathways of fat injection may be parallel or crisscrossed, as needed. Fat injection may be carried out as a reversal of fat extraction in liposuction. During the injection, incremental change in the contour is correlated with the amount of fat injected. A skin pinch test is used to assess the thickness of the operative sites. Although a small degree of overcorrection is acceptable, excessive tissue turgor or overcorrection should be avoided.

Postoperative Care

The postoperative care of patients who have undergone corrective liposuction and fat grafting is similar to that given to patients who have undergone primary liposuction. If there is any chance that a compression garment may apply uneven pressure to the area that has received fat grafting, such a garment is not used. Postoperative manual massage is applied to areas with prolonged induration and firmness.

Outcomes

In most properly selected patients, secondary procedures for postliposuction contour irregularities are expected to correct or improve deformities. I reported on 22 patients with 43 areas of postliposuction contour irregularities; 2 areas were treated with dermolipectomy, 22 areas were treated with liposuction only, and 19 areas were treated with fat grafting in combination with liposuction. Ninety-five percent of the areas showed improvement, nearly complete correction, or complete correction. Five percent of the areas had overcorrection consisting of minor depressions. The quality of the outcome was also related to the severity of the postliposuction contour irregularities. Thirty-one percent of the areas with major contour irregularities (defined as an area greater than 100 cm², with greater difficulty of correction and increased severity of visual impact) had nearly complete or complete correction. Forty-seven percent of areas of minor contour irregularities had nearly complete or complete correction. Most patients required one or two corrective procedures; two patients required three procedures. The average number of procedures required was 1.4 per patient. The only complication noted was hyperpigmentation in the skin of one patient.

Results

Correction of Contour Irregularities, Protuberances, and Depressions

This 55-year-old woman underwent simultaneous liposuction of the abdomen and mini-abdominoplasty. Her surgeon performed additional liposuction to correct contour irregularities. She presented with multiple contour irregularities in the abdomen 3½ years after the initial operation. Examination revealed an uneven contour, protuberant areas in the lower abdomen, and areas of depression below the umbilicus.

A corrective procedure was performed with the patient under general anesthesia. No wetting solution was used in the abdomen. Umbilical incisions and three lower abdominal incisions were made. A 3 mm Mercedes-type cannula was used to aspirate areas of protuberance in the lower abdomen and around the periumbilical and supraumbilical areas. Liposuction was tapered from the point of maximal protuberance into areas of maximal depression. The adhesions beneath the areas of depression were freed by passing a liposuction cannula without suction to create space for fat grafting.

To obtain fat for grafting, liposuction of the medial thighs and the medial knees was performed after infiltration with 0.25% lidocaine with 1:400,000 epinephrine. With an intravenous catheter, 35 cc of fat was injected into the areas of depression. Additional minor liposuction was performed around the periumbilical area 5 months later.

Improvement is evident 22 months after the major corrective procedure. The result remained stable 9 years and 10 months later, when the patient was 68 years of age. In the meantime, she had an upper abdominal dermolipectomy to correct upper abdominal skin laxity.

Correction of Contour Irregularities, Disproportion, Protuberances, and Indentations

This 55-year-old woman had multiple areas of postliposuction contour irregularities, including bilateral posterior iliac regions, her lateral thighs, and the lateral hip areas. Her surgical correction consisted of liposuction around the areas of indentation and autologous fat grafting. The amount of fat grafting to each area was as follows: 60 cc each to the right and left posterior iliac crest areas, 110 cc to the left lateral hip, 95 cc to the left upper lateral thigh, and 95 cc to the right upper thigh.

Two years and 4 months after the corrective procedure, the indentations in the right and left iliac crest areas, the left lateral hip, and upper thighs were improved, as seen in the posterior and lateral views.

Correction of Areas of Linear and Circular Depression

This 38-year-old woman had undergone liposuction of the thighs, and 2½ years later she presented for corrective surgery. At the time of our consultation, she had already undergone one corrective procedure. On physical examination, we noted linear depressions in the posterior thighs and circular depressions in the lateral thighs.

The preoperative markings include solid red areas, which indicate areas of maximum depression and indentation. Areas of protuberance are indicated with multiple black X's. Transitional zones were noted between the areas marked red and black. Surgery was performed with the patient under general anesthesia and in the prone position. No local anesthetic was injected. Several incisions were made in the buttock crease, lateral thigh, and distal posterior thigh in the midline. Areas of protuberance were aspirated with a 3.7 and 2.4 mm Mercedes-type cannula. A total of 20 cc of aspirated fat was injected into the areas of depression and indentation. Both a blunt-tipped cannula and a sharp needle were used to inject the fat into the depressed areas. Three additional minor corrective procedures were performed over the next several years, and the patient underwent liposuction in the hip area.

Her improvement remained stable 11 years and 10 months postoperatively.

Correction of Indentation in Male Breasts

This 54-year-old man underwent reduction of gynecomastia with UAL. He developed indentations of the right and left breasts; the right side was more pronounced than the left. He also had adhesion of the nipple-areola complex, manifested by retraction during voluntary contraction of the pectoralis major muscle. The adhesion resolved spontaneously. He underwent corrective surgery 3½ years after the original surgery.

The procedure was performed with the patient under intravenous sedation. The fat was aspirated from the right and left flank with a 3 mm cannula; 9 cc was aspirated from the right and left chest with a 1.8 mm cannula, and 35 cc of fat was infiltrated into the right breast, including the subareolar area, with both an 18-gauge needle and a blunt-tipped cannula. At 15 months postoperatively, good correction is evident.

Correction of Large Soft Tissue Deficiency of Thighs and Buttock Ptosis

This 46-year-old woman underwent liposuction of the lateral, medial, and anterior thighs and lower leg. She developed contour irregularities at multiple sites. She was particularly concerned with changes in the lateral and medial thighs, around the knees, and in the posterior calves.

Corrective surgery was performed with the patient initially positioned supine. Approximately 200 cc of 0.125% lidocaine with 1:800,000 epinephrine was injected into various sites before fat was aspirated. The recipient areas were pretunneled before the fat was injected with a blunt cannula. Liposuction was performed in the upper medial thighs, medial knees, and anterior-superior knees. The fat was injected into the right anterior thigh (23 cc), right and left midmedial thighs (10 and 55 cc,

respectively), and the abdomen (25 cc). The patient was then placed in a prone position, and liposuction was performed on the posterior thighs. Fat was injected into the right and left posterior lateral thighs (90 and 100 cc), posterior gluteal folds (40 and 20 cc), and the calves (25 and 28 cc). The total amount of fat aspirated was 480 cc; the total amount of fat injected was approximately 420 cc.

Twenty-five months later, improvement of the contour in the medial, lateral, and posterior thighs, and around the knees is evident. The patient returned to the operating room for additional improvement in the outer thighs, buttocks, knees, and legs.

Liposuction was performed in the abdomen, anterior and medial thighs, anterior-superior knee, and anterior proximal legs. The arms, waist, hips, and the right mid-posterior thighs were aspirated as additional fat donor sites. Fat was injected into

the abdomen (40 cc), right anterior thigh (60 cc), left anterior thigh (30 cc), left leg (20 cc), right leg (10 cc), right and left lateral thigh, gluteal folds and right posterior upper thigh (400 cc). A blunt cannula was used for fat grafting at all the sites. At the right lateral thigh, upper posterior thigh, and gluteal fold, 16- and 18-gauge needles were used in addition to the blunt cannula.

The postoperative result 13 months after the second procedure shows that there is more fullness in the lateral and upper posterior thighs. There is reversal of the soft tissue deficiency and improvement in the sagging at the buttock–upper thighs junction.

Correction of Contour Irregularities and Depressions

This 44-year-old woman underwent liposuction of the thighs, knees, and buttocks 1 year before presentation. Circular, linear, and irregularly shaped depressions were noted in the medial, lateral, and anterior thighs.

Preoperative surgical markings of areas of maximal indentation were made (*solid red*). Intermediate areas of indentation were marked with parallel red lines. Red circles indicated areas with a smaller degree of indentation. Areas of protuberance were crosshatched or marked with X's. Anteromedial thighs and knees were aspirated with the patient in the supine position under general anesthesia. The aspirated fat was injected into the area of depression using 14- and 16-gauge intravenous catheters. The patient was then placed in the prone position, and 1400 cc of fat was aspirated from the thighs; 200 cc was injected into various areas of indentation and depression.

Fourteen months after the first corrective procedure, several areas of the thighs appeared full and out of balance with other areas of the thighs and the body. Some areas of the thighs had received less liposuction than others up to this point; her hips and abdomen also appeared full. Additional liposuction without fat grafting was performed 14 months later.

The patient is shown 4 years and 10 months after the first corrective procedure. Good improvement is noted in the anterior, medial, and lateral thighs and in the knees. A slight indentation persisted in the left lateral thigh.

The patient's results remain stable 13 years and 4 months postoperatively.

Correction of Diffuse Irregular Indentations, Protuberances, and Skin Excess

This 45-year-old woman underwent liposuction of multiple body areas; the tumescent technique was used. She underwent subsequent revision. A total of 1500 cc of aspirate was removed from the abdomen during the two previous procedures. At our consultation, we noted diffuse, irregular, circular, and oval indentations in the lower abdomen, with redundant skin on the upper abdomen.

Preoperative surgical markings identified areas of protuberance in the right lower lateral abdomen, suprapubic area, supraumbilical areas, and multiple areas of indentation in the lower abdomen. The protuberant regions were infiltrated with 0.25% lidocaine with 1:800,000 epinephrine and treated with SAL. An internal ultrasound device was used to create space for fat grafting in the densely fibrotic tissue. The LySonix 2000 cannula at a power setting of 2 was introduced into the subcutaneous space of the lower abdomen caudal to the umbilicus after wetting solution was infiltrated. The use of an ultrasound cannula permitted breakthrough of the scar, which was confirmed by passing a blunt 2.4 mm cannula without suction. No fat was aspirated during application of the ultrasound. Fifteen cubic centimeters of fat was transferred into the lower abdomen. The deeper level was injected using a blunt-tipped cannula. Sharply circumscribed indentations were injected with an 18-gauge needle at the superficial (subdermal) level. Postoperatively, the abdomen was covered with nonsticky foam and an elastic garment.

Twenty months postoperatively, some improvement in contour is evident. (NOTE: UAL is rarely used in corrective liposuction to maximize fat preservation.)

Concluding Thoughts

The best treatment of postliposuction contour irregularities is *prevention*. The optimal method of fat collection, processing, and transfer remains to be determined. The technique described in this chapter is relatively simple, practical, and does not require elaborate equipment. With appropriate patient selection and proper application of the various surgical techniques, most cases of postliposuction contour irregularities can be improved by various degrees. Multiple procedures may be required for complicated cases.

Clinical Caveats

In patients with complex postliposuction contour irregularities with volume deficiency, surgical correction consists of liposuction of areas of protuberance and around areas of depression with concurrent fat grafting.

Dermolipectomy is indicated for patients with redundant or extensively altered skin.

A detailed contour map delineates areas of maximal protuberance and depression and adjacent transitional zones.

Pretunneling before corrective liposuction facilitates accurate fat extraction.

A blunt-tipped cannula without suction is passed beneath the area of depression to make space for fat grafting if there is dense fibrosis.

Incisions are placed to create the most direct approach to areas requiring correction.

The solidity of the material for fat grafting is maximized by avoiding or minimizing the injection of wetting solution.

During secondary or primary liposuction, if overresection of fat is observed, the volume deficiency should be replaced with immediate fat grafting.

A submaximal vacuum setting (26 to 28 mm Hg) is used to obtain fat for grafting.

Avoid or minimize injection of wetting solution into areas requiring correction so the existing contour can be better visualized.

In densely fibrous areas, fat may be more precisely deposited using sharp needles.

Fat is injected superficially or deep, depending on the location of the soft tissue deficiency.

Overresection should be avoided in secondary lipoplasty.

Multiple procedures may be required for treatment of postliposuction contour irregularities.

Liposhifting offers alternatives to fat grafting in some deformities.

Annotated Bibliography

Chang KN. Long-term results of surgical correction of postliposuction contour irregularities. *Plast Reconstr Surg* 109:2141-2145, 2002.

Long-term surgical results, ranging from 5 years to 13 years and 4 months, are presented in five patients. The beneficial results of the procedures, which have been previously reported, continue to be observed during the follow-up.

Chang KN. Surgical correction of postliposuction contour irregularities. *Plast Reconstr Surg* 94:126-136; discussion 137-138, 1994.

Surgical treatment of postliposuction contour irregularities with secondary liposuction and fat grafting and the outcome in 43 areas of the body in 22 patients are presented. The surgical results involving the lateral, posterior, and medial thighs and the abdomen, hips, and waist in 5 patients are illustrated.

Fodor PB. Secondary lipoplasty. *Aesthet Surg J* 22:337-348, 2002.

The author presents a clinical classification of candidates and indications for secondary lipoplasty. The results of secondary liposuction, dermolipectomy, and fat grafting in the abdomen, lateral buttocks, and thighs in three patients are detailed.

Rohrich RJ, Smith P, Marcantonio DR, Kenkel JM. The zones of adherence: role in minimizing and preventing contour deformities in liposuction. *Plast Reconstr Surg* 107:1562-1569, 2001.

This article identifies five zones of adherence to avoid in the trunk and extremities to prevent contour deformities when performing circumferential liposuction. These zones are the lateral gluteal depression, gluteal crease, distal posterior thigh, midmedial thigh, and infralateral iliotibial tract. Two patients who underwent fat grafting in the buttocks and posterior, lateral, and medial thighs are presented.

Saylan Z. Liposhifting instead of lipofilling: treatment of postlipoplasty irregularities. *Aesthet Surg J* 21:137-141, 2001.

Saylan presents a technique in which the subcutaneous fat adjacent to the area of depression is loosened with a specially designed cannula and shifted to adjacent areas of depression by external pressure. No fat is removed from or reintroduced into the patient.

Wall S. SAFE circumferential liposuction with abdominoplasty. *Clin Plast Surg* 37:485-501, 2010.

The author presents his separation, aspiration, fat equalization (SAFE) liposuction technique and associated instruments, which are used in both primary and secondary liposuction. The fat is loosened and redistributed with a power-assisted device.

CHAPTER 89

Special Problems in Reoperative Body Contouring

JOSEPH F. CAPELLA

Reoperative procedures are an important component of a body-contouring practice. There are many factors leading to the need for revisional surgery; most are the result of an unexpected outcome, but some can be related to the plastic surgeon's choice of primary procedure. In an effort to accommodate a patient's busy lifestyle, both the patient and plastic surgeon may be driven toward procedures with the shortest recovery period or the shortest scar. Less-invasive procedures are often innovative and are often reported to produce results similar to more invasive procedures—but frequently have limited supportive data. It is essential that all plastic surgeons, particularly those early in their careers, have a clear understanding of the procedures and clinical scenarios that are most likely to result in patient dissatisfaction and the need for revision.

In this chapter I have selected several body-contouring cases from different regions of the body that resulted in the need for revisional surgery but might have been avoided with a different primary procedure.

Abdomen, Thighs, and Buttocks

Lower Body–Contour Deformities After Liposuction

Contour deformities following liposuction of the lower body in a postpartum or postbariatric patient are among the most frequent complaints leading to reoperative surgery, in my experience. Almost all women have some weight gain during pregnancy, some more than others, leading to an extended period of soft tissue expansion of the abdomen and to some degree the hips, thighs, and abdomen. After delivery, much if not all of the weight is lost and soft tissues retract in varying degrees, depending on multiple factors, including age, number of pregnancies, the amount of weight gained and lost, and the woman's sun exposure, complexion, and tobacco consumption. A postbariatric patient undergoes a similar but more exaggerated experience. However, the result for the two groups is similar: excess soft tissue, and tissues with poor elastic qualities. As has been described by others, an appropriate amount of fat in the soft tissues of the body is an essential element of a youthful appearance. In a postpartum or postbariatric patient, excess fat may be a component of the contour deformity; however, excess soft tissue and limited elasticity are likely to play a larger role. Liposuction alone for these patients will often result in an increase in contour irregularities.

This 36-year-old woman underwent a 32 kg (70-pound) weight change with pregnancy. Her postpartum contour concerns were addressed on two occasions by another physician with liposuction of the abdomen, thighs, and buttocks. She came to me dissatisfied with her extensive contour deformities and loose skin. I performed a circumferential lower abdominal, thigh, and buttock lift. She is shown 30 months postoperatively.

The treatment of postliposuction contour deformities is challenging. An excisional procedure will conceal the fatty deficits by tightening the soft tissue. Injection of fat may be useful for small areas of fat deficiency but is unlikely to be practical over larger areas of the body and when soft tissue excess is the primary problem. My preference is to wait at least 6 months before attempting to address postliposuction deformities with excisional procedures. A history of excessive liposuction, particularly to the anterior abdominal wall, may compromise blood supply to these tissues.

Overall, I have found excisional procedures to be very useful, particularly with regard to deformities closer to the waistline.

Postbariatric Lower Body–Contour Deformities After Abdominoplasty Alone

Following weight loss, patients often present to a plastic surgeon with multiple complaints involving the abdomen, thighs, and buttocks. For both men and women, the abdomen is usually of greatest concern. The thighs and buttocks may be of concern, but the degree of soft tissue excess in these areas is often not completely appreciated by the patient unless he or she is examined in front of a mirror while upward traction is applied to the soft tissues of the lower body.

Postbariatric patients are often advised to undergo abdominoplasty alone or with liposuction to the hips and thighs. These traditional procedures usually only partially address the deformities that result from weight loss and in some instances may produce an unnatural-looking body contour. Abdominoplasty and liposuction can accentuate the soft tissue excess of the hips, thighs, and buttocks and often produce standing cones of tissue.

This 50-year-old man lost 59 kg (130 pounds) following gastric bypass surgery and underwent an abdominoplasty. He came to me with concerns about laxity along the lower abdomen and mons pubis and excess skin and fat along the hips and buttocks. In addition, he thought that his lower abdominal scar was too high. This man's contour deformities are typical of those following abdominoplasty in a massive-weight-loss patient. I addressed his concerns by performing a lower body lift; that is, a transverse thigh and buttock lift and a medial thigh lift with a vertical component. He is shown approximately 3 months after surgery.

Circumferential techniques are far more effective procedures for addressing the deformities of a massive-weight-loss patient; a more balanced aesthetic result can be achieved, and the standing cones of tissue can be avoided. In addition, the infraumbilical portion of the abdomen can usually be made tighter than with abdominoplasty alone, because there is no limitation in scar length.

The Medial Thigh Lift Approach: Thigh–Perineal Crease Alone Versus Thigh–Perineal Crease Plus a Vertical Component

The medial thighs can be of great concern for both postpartum and postbariatric individuals. These patients will often come in for a consultation, stand in front of a mirror, and elevate their medial thighs toward the groin crease, requesting that this be replicated by a surgical procedure. Many plastic surgeons approach medial thigh–lifting techniques with great hesitation. The undesirable outcomes associated with these procedures are well known: labial distortion resulting from excessive tension, descent of scars from the thigh–perineal crease, descent of the pigmented tissues of the groin onto the proximal thigh, and limited or no improvement of the medial thigh contour. Nevertheless, patients are eager to have some kind of intervention. Elevating and securing the sagging medial thigh tissues to an immobile structure such as Colles' fascia appears to be an effective approach to this problem.

This 33-year-old woman lost 78 kg (172 pounds) after a gastric bypass procedure. I initially performed a body-lift procedure on her (simultaneous abdominoplasty and thigh and buttock lift). She was satisfied with the results but had remaining concerns about her medial thighs. I described the thigh–perineal approach to performing a medial thigh lift but explained that a more aggressive approach involving a scar along her medial thigh extending to her knee would result in a better outcome. She was adamantly opposed to this lengthy scar, and at that point in my career, I was receptive to whatever choice was taken by the patient regarding the medial thighs.

I performed a medial thigh lift limited to the thigh perineal crease. The results are self-evident (*left*). The scars have descended, the labia have been distorted, and aesthetically there appears to be no improvement in her result.

The same patient is shown 2 years after a body lift and 6 months after a medial thigh lift with a vertical component (*right*). In addition to producing an improved aesthetic result, the deformity at the thigh–perineal crease has been corrected by the addition of the vertical component.

This case illustrated very clearly to me the factors contributing to the medial thigh deformity in individuals after significant weight loss. There are three elements from outside the medial thighs that affect the medial thighs: descent of the mons pubis toward the medial thighs, descent of the buttocks toward the medial thighs, and inferomedial rotation and descent of the thighs toward the medial thighs. These three consequences of significant weight loss are very effectively addressed by circumferential body-lifting procedures. However, circumferential excess at the thighs is not addressed by body-lift procedures or medial thigh-lift techniques limited to the thigh–perineal crease. Medial thigh lifts with a vertical component very effectively address this remaining excess and produce a far better aesthetic result.

In a weight-loss patient who has undergone a circumferential body-lifting procedure, the addition of a medial thigh lift limited to the thigh–perineal crease is usually of limited benefit. Removing excess tissue in only a vertical vector along the medial thighs and securing the thigh flap to an immobile structure (Colles fascia) will likely produce a suboptimal aesthetic outcome. In an individual who has undergone significant weight loss, the combination of inelastic qualities of soft tissues and the normal and necessary thigh abduction of everyday activities will eventually result in either the descent of the thigh–perineal scar and labial distortion, or recurrence of soft tissue excess along the medial thighs.

Arms

The arms are visible in everyday activities, and their appearance is important to individuals of all ages. Unfortunately, the consequences of many variables, including weight loss, sun exposure, and tobacco consumption, greatly affect the contours of the arms. The ready visibility of the arms makes patients and plastic surgeons particularly averse to scars in this region.

Arm Contour Deformities After Liposuction

As in the rest of the body, poor skin elasticity and excess soft tissue in the arms is likely to lead to a poor outcome after liposuction. From my own experience and from examining patients from other practices, postpartum and postbariatric patients usually do not benefit from arm liposuction alone. The deformities from these procedures may not be immediately recognizable but may appear later with aging and environmental exposure. The effects of skin retraction from liposuction procedures alone are limited.

This 21-year-old woman lost 82 kg (180 pounds) after gastric bypass surgery. She subsequently underwent laser-assisted liposuction of the arms. She presented to my practice with concerns about her arm contour deformities and sagging skin. I performed a brachioplasty that included concomitant liposuction and excision of soft tissue. She is shown 6 months postoperatively and is very pleased with her results, although she has gained significant weight since her surgery.

In many areas of the body, I have found the combination of liposuction and soft tissue excision to be very effective. Liposuction facilitates greater soft tissue excision and provides a readily identifiable plane of dissection.

Short-Scar Versus Traditional Brachioplasty Procedures

The rapid increase in the number of bariatric procedures in the United States and abroad has made brachioplasty a commonly performed surgery for many plastic surgeons. Although before 2000 the procedure was rarely performed by any plastic surgeons, more than 14,000 brachioplasties were performed in the United States in 2009. Excisional procedures are generally accepted as the treatment of choice for individuals who have lost weight, but multiple variations of brachioplasty have been described to minimize or eliminate the scar along the arm (see Chapter 82).

This 57-year-old postpartum woman had lost 20 kg (45 pounds) 10 years earlier through lifestyle changes. Eight months before she came to me, she had undergone liposuction of the arms, and 4 months before she presented, she had a brachioplasty with the scar limited to the proximal arm and axilla. She was disappointed with the results and thought that her best potential arm contour had not been achieved. I performed a traditional brachioplasty with extension of the arm scar to the medial epicondyle. She is shown 3 months postoperatively.

In the obese state, fat is stored in characteristic areas for both men and women. The soft tissues in these areas expand to accommodate fat. The longer the duration of obesity and the greater the weight reached by the patient, the poorer the tissue elasticity will be and the more excess soft tissue will be present. In both men and women, fat along the upper extremity is stored primarily at the axilla and proximal arm. The resulting deformity from weight loss requires that excess tissue be removed along a horizontal vector at the arm. The length of the arm scar required to address the arm contour deformity is determined by the degree of deformity present and the quality of the result desired by the patient.

Concluding Thoughts

The effects of aging, the environment, pregnancy, excessive weight, and weight loss will diminish the elasticity and quality of the soft tissue of the body, which in turn leads to contour deformities. Despite significant advances in plastic surgery, the body-contouring techniques available to us consist primarily of the removal and placement of soft tissue and prostheses. No substantial gains have been made in the way of improving soft tissue quality and elasticity. Thus it is unlikely in the near future that the lengthy scars often needed for effective body contouring can be avoided. Much of our clinical effort in this regard should be directed scar quality and perceptibility and educating our patients about the appropriate procedures available to achieve their goals.

Clinical Caveats

The need for revisional surgery is sometimes affected by the selection of the primary procedure.

Liposuction can produce contour deformities in individuals with excess soft tissue and poor skin elasticity.

Contour deformities secondary to liposuction can be treated in varying degrees by soft tissue excisional procedures.

Abdominoplasty and liposuction alone are unlikely to produce an optimal result in the weight loss patient.

Medial thigh-lift procedures limited to the thigh-perineal crease have limited utility and can be associated with significant complications in a weight-loss patient.

Circumferential body lifting procedures are often an integral component of correcting the medial thigh-lift deformity in a weight-loss patient.

Careful patient selection is critical to effectively implementing short-scar techniques in brachioplasty.

Lengthy scars are likely to be an important part of some body-contouring procedures until substantial advances are made in the science of improving the elasticity of soft tissue.

Annotated Bibliography

Abramson DL. Minibrachioplasty: minimizing scars while maximizing results. *Plast Reconstr Surg* 114:1631-1634; discussion 1635-1637, 2004.

A short-scar brachioplasty or minibrachioplasty technique is described that limits the scar to the axilla and proximal arm. Eight patients were treated with the technique. Brachioplasty techniques with scars limited to the proximal arm are likely to have limited utility in weight-loss patient. Very careful patient selection is critical to properly implement short-scar techniques in brachioplasty.

Baroudi R. Reoperation after liposuction and body contouring surgery. In Grotting J, ed. *Reoperative Aesthetic & Reconstructive Surgery*, 2nd ed. St Louis: Quality Medical Publishing, 2007.

The author reviews complications following a wide array of body-contouring procedures. Causes of patient dissatisfaction after liposuction are discussed, such as insufficient or excess fat removal and skin irregularities and laxity resulting from poor skin retraction. The effects of weight fluctuations after liposuction are illustrated. The use of secondary liposuction, fat injection, and soft tissue excision to address contour irregularities is described.

Capella JF. Body lift. *Clin Plast Surg* 35:27-51; discussion 93, 2008.

I review my first 425 body lifts (simultaneous abdominoplasty, thigh, and buttock lift). The indications for the technique and the limitations and disadvantages of performing abdominoplasty alone in postbariatric patients are discussed. Multiple cases are provided, exemplifying the varied presentation of this patient population. A detailed review of complications after a body lift describes the association between body mass index and pulmonary embolism.

Capella JF. Brachioplasty. Presented at the Baker Gordon Symposium, Miami, Feb 2005.

At this conference I discussed the reasons that medial thigh–lift procedures limited to the thigh–perineal crease are unlikely to be effective in individuals after weight loss. The variables contributing to the medial thigh deformity were reviewed, including ptosis of the mons pubis, inferomedial descent of the thighs, buttock ptosis, and horizontal or circumferential excess thigh soft tissue. Use of a circumferential body lift and medial thigh lift with a thigh–perineal crease and medial longitudinal component to address the medial thigh deformity was reviewed.

CHAPTER 90

Reflections on the Art of Aesthetic Surgery

FOAD NAHAI

Aesthetic surgery is an art, a visual art. Despite efforts to quantify results and set standards to measure outcomes, our evaluations remain subjective. Beauty is interpreted subjectively by patients and surgeons: the patient's idea of beauty may not be the same as the surgeon's. There are also significant ethnic and cultural differences that define our concept of what features are considered attractive. High-arched eyebrows, the ideal in some cultures, may seem exaggerated or overdone in others. The ideal breast size varies considerably from culture to culture and from one geographic area to another. Whereas a plump or full figure is admired in some regions, in the United States the media promote a slender figure as the ideal. A successful aesthetic surgeon who is mindful of these differences actively elicits the patient's concept of beauty and expectations for a result.

Aesthetic surgery adapts to the times; it is a part of our culture, reflecting current fashions, trends, and fads. Occasionally these trends become exaggerated and divorced from normal standards of appearance and beauty. This can be seen in frozen, expressionless foreheads overtreated with Botox, or excesses in lip augmentation where these delicate structures are inflated beyond proportion, or augmented breasts with exaggerated upper pole fullness, a characteristic seen so frequently that some people accept this as normal. It is our responsibility to educate our patients and the public so that they understand the difference between a normal enhanced appearance and one that has been unnaturally altered.

Aesthetic surgery is also, first and foremost, a surgical discipline, and in that respect no different from any other surgical specialty. It cannot be taught overnight or practiced effectively without a strong surgical background. Aesthetic surgery does not exist in a vacuum. This is a discipline based on sound knowledge of anatomy and physiology combined with an understanding of the psychosocial aspects of altering the face and body. Principles of surgery, specifically physiologic responses to surgical trauma, wound healing, and the prevention and management of complications, apply as much to aesthetic surgery as to any other surgical specialty. Years of experience in basic surgical technique, training in reconstructive surgery, and exposure to detailed anatomy in the laboratory are prerequisites for practicing aesthetic surgery. For me this experience began in the anatomy lab, culminating in an honors degree in anatomy, followed by years spent restoring form and function through anatomic research and clinical applications. My current interest in aesthetic surgery was a natural extension of this reconstructive and anatomic training. What I have come to realize is that whether we are restoring form and function or enhancing body or facial appearance, we are guided by the same aesthetic principles and goals. Expertise and competence in aesthetic surgery is not gained through a weekend course, a few days spent observing an expert, or an hour viewing a DVD.

I love this specialty because there are so many ways of solving problems, regardless of whether we are rejuvenating the aging face, correcting changes in the shape and size of the breast, or recontouring the body. Each of the approaches is right for the right patient. Because the specifications will vary for each individual, depending on the patient's physical situation and desire for change, the surgeon should be skilled in a number of different techniques, but not necessarily all, which can be applied or modified accordingly. Clinical decision-making, which contributes to patient satisfaction, must also take into account the patient's motivation for seeking aesthetic surgery, degree of concern over the perceived problem, and expectations. Choices can only be made after listening to the patient and setting goals that are in balance with his or her lifestyle. A patient seeking facial rejuvenation who has only a few days for full recovery and whose lifestyle will not permit sun avoidance is obviously not a candidate for a fully invasive face lift or laser resurfacing. In this situation, the patient must either agree to temporarily alter that lifestyle and have the invasive procedures or be willing to accept a less than ideal result with injectables, other noninvasive procedures, and skin care.

The pendulum swings; fads come and go. We should not precipitously embrace every new technique, treatment, or technology that is advanced until each has been evaluated, its value, safety, and efficacy established, and the appropriate role or indications defined. Regrettably, many manufacturers are promoting their products directly to the public before physicians have the opportunity to scientifically evaluate them to verify their safety and efficacy. I am concerned that these companies no longer view us as their customers, preferring to drive demand by targeting the public, who lack the scientific background for judging these products and may be more gullible and accepting of exaggerated claims. To ensure that our patients receive the best care with the safest products, we need to find a way to get back into the mix and to resume our proper role in monitoring this process.

Aesthetic surgery, as is true of all surgery, carries risks. When I discuss these with my patients, I advise them to forget the word "cosmetic" and remember the word "surgery." I explain that all surgery, even in the best of hands, carries risks. The best we can offer our patients is reduction of this risk by taking the necessary measures to minimize complications and morbidity. The patient is responsible for selecting the surgeon; the surgeon is responsible for the patient's safety, comfort, and privacy.

Ensuring patient safety and minimizing risk begins with the initial consultation and history-taking and continues with preoperative preparation, intraoperative measures, postoperative care, and follow-up. Patient selection is a key part of this process. The medical history should elucidate factors that will affect outcomes in aesthetic surgery, such as smoking, hypertension, other general medical conditions, medications, allergies, and history of psychological problems. If necessary, or if there is any doubt about the patient's health, the patient should be referred to his or her primary

care physician, counselor, or psychiatrist for a thorough evaluation before any operation is undertaken.

The type and length of procedure and the combination of procedures have an impact on patient safety. Where the operation is performed (the physician's office, a freestanding certified outpatient surgical facility, or the hospital) is also relevant. These decisions are normally made by the surgeon with little if any input from the patient. However, given concerns about expense, and with the advent of the fascination by the media and public with extreme makeovers, where multiple procedures are performed simultaneously for a complete, rapid transformation, it is not unusual today for patients to request or even demand multiple simultaneous procedures. Although in some patients this may be safe, it is prudent for the surgeon to point out the increased risks of these long, multiprocedure operations. Patient safety should not under any circumstances be compromised by financial concerns or succumb to the patient's insistence that everything be done at once. Similarly, the choice of facility where the operation will be performed should be based on sound surgical judgment rather than financial concerns.

It is the role of the surgeon working with the surgical team to coordinate patient comfort and safety in the operating room. This includes proper functioning of all instruments and equipment, positioning and protection of pressure points, protection of the cornea, appropriate placement of grounding plates, maintenance of patient body temperature, and deep venous thrombosis prophylaxis, to mention only a few.

After the operation, the patient should be cared for in an appropriate setting. This will range from their home to overnight or longer in a suitable overnight facility or a hospital. This decision is based on the type of procedure and the patient's general medical condition. For multiple body-contouring procedures, I recommend hospitalization with at least one overnight stay. For facial aesthetic surgery, I prefer to take care of them in our own freestanding certified surgical center with at least one overnight stay in our facility. Breast augmentations and small volume liposuction are outpatient procedures performed in our surgicenter; however, I do ask these patients to stay within 20 minutes' reach of our office for the first postoperative night. Although immediate complications are very rare in this group, I do not think it is wise to allow them to travel long distances, and I prefer to have them in close proximity in the unlikely event of a complication.

Postoperative patient management after discharge from the facility should include directions for the specific procedure and general information on the prevention and management of postoperative nausea and vomiting, pain and discomfort, and temperature changes. The patients are also instructed to look for any sudden or unusual swelling or change in the operative site which may indicate hematoma. All patients undergoing surgical facial rejuvenation remain in our facility overnight and are continuously monitored for elevation of blood pressure, nausea, and pain and discomfort.

Trends in aesthetic surgery are toward procedures that are less invasive, less expensive, require less recovery, have less morbidity, and require less time. However, less is not necessarily more; in fact, it may be less, except in younger individuals who are seeking aesthetic surgery in ever-larger numbers. For some of these patients, skin care, injectables, and noninvasive treatments can be as effective as a full face lift in older individuals. These trends are growing rapidly as younger and younger patients with minimal or moderate aging changes seek early rejuvenation and as older individuals increasingly request less-invasive procedures. Therefore it seems only logical to predict that the demand for complex, extensive surgical procedures requiring prolonged recoveries has declined and will continue to decline. However, this prediction does not hold true for all patients. There is an emerging new group of candidates for aesthetic surgery, massive-weight-loss patients, whose only effective options are all extensive, complex facial and body-contouring procedures.

Medical tourism is another trend that has grown in popularity, in some cases posing a potential threat to patient safety. Contrary to what we knew as medical tourism in the past, where wealthy individuals from developing countries travelled to Western Europe and North America in search of excellence, today the trajectory has been reversed as patients travel to developing countries in search of bargains in health care in general and in aesthetic surgery in particular. Clearly, there are many well-qualified, skilled physicians and first-rate facilities in these developing countries, but the fact remains that it is a risky business when patients choose caregivers based solely on price considerations. Regrettably, there are numerous unscrupulous, untrained practitioners who offer bargain prices to unwitting consumers; these practitioners are frequently aided by tour organizers, vacation resorts, and even national governments who promote these services while downplaying the serious nature and risks of surgery. Instead, they focus on the vacation and the tourist attractions available, conveniently glossing over issues of recovery and the potential complications associated with any surgical intervention. Although we cannot slow this trend, we can provide some balance and help to educate the public and our patients about potential dangers. For those of us who treat patients who travel long distances to see us, it is essential to make sure that these patients are well informed and that arrangements are made for safe follow-up care on their return home.

Aesthetic surgery is evolving. Procedures are continually being revised and refined to offer our patients the best care possible. As new techniques and technologies are introduced, established techniques are reevaluated and even abandoned. This evolutionary process is necessary; it should and will continue. It is my hope that this second edition will mirror the ongoing evolution and contribute to the advancement of our specialty. Ultimately, aesthetic surgery is an art form; it is creative, dynamic, and for me, it represents completion of my personal lifelong fascination and passion with the practice of plastic surgery.
